ETEC also causes watery diarrhea characterized by severe intestinal water secretion by producing plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin. The heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa as cholera toxin. Heat-labile toxins increase chloride secretion via activation of cAMP. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea.[22] Heat-stable toxin is thought to be nonantigenic and produces watery diarrhea by acting on the small intestine.

Rotavirus induces changes in transepithelial fluid balance, and causes malabsorption as a consequence of destruction of the epithelial lining of intestine, and vascular damage and ischemia in villi. Once rotavirus infects small intestinal villus cells, viroplasms are formed and its toxin, nonstructural protein 4, is released. The viral enterotoxin increases intracellular calcium, and the increase in calcium disrupts microvillus cytoskeleton, as well as barrier function. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.[23]

Inflammatory diarrhea is caused by two groups of organisms—enterotoxin-producing, noninvasive bacteria (eg, EAEC, EHEC) or invasive organisms (eg, *Campylobacter* spp., *Salmonella* spp., *Shigella* spp.). The enterotoxin-producing organisms adhere to the mucosa, activate cytokines, and stimulate the intestinal mucosa to release inflammatory mediators. Invasive organisms, which can also produce enterotoxin, invade the intestinal mucosa to induce an acute inflammatory reaction, involving the activation of local and systemic cytokines and inflammatory mediators.

Ingestion of as few as 10 to 200 viable organisms of the *Shigella* spp. causes disease in healthy adults.[18,19] *Shigella* multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Inflammatory diarrhea is caused by the pathogens invading the epithelial barrier through M cells where they encounter and eliminate macrophages. The destruction of macrophages after emergence from M cells causes an initial release of interleukin (IL)-1β. This initial inflammatory process is exacerbated by free bacteria binding to toll-like receptor that causes the production of IL-6 and IL-8. Both IL-1β and IL-8 attract polymorphonucleocytes.[24] Release of polymorphonucleocytes activates chloride secretion and subsequent diarrhea. Degranulation and release of toxic substances by neutrophils cause ulceration of the epithelium, distortion of the crypts, death to intestinal epithelium, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.[25] Microabscesses eventually may coalesce, forming larger abscesses. *Shigella* will frequently affect the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to a lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin or Shiga toxin, which can lead to HUS.[14]

The pathogenicity of EHEC is related to the production of Shiga-like toxins, so named because of their resemblance to the Shiga toxin of *S. dysenteriae*.[21] The cytotoxic effect of Shiga-like toxins disrupts the mucosal integrity of the large intestine, causing diarrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that could eventually lead to HUS.

CLINICAL PRESENTATION

Gastroenteritis is an illness characterized by diarrhea, which may be accompanied by nausea, vomiting, fever, and abdominal pain. For effective diagnosis and management, it is important to distinguish noninflammatory diarrhea that produces watery diarrhea from inflammatory diarrhea or dysentery. Most enteric pathogens produce acute diarrhea and pathogens associated with dysentery will often result in grossly bloody stools and mucus. Systemic symptoms of gastroenteritis, such as fever, are often associated with dysentery of infectious origin. Symptoms of enteric pathogens that cause watery and dysentery diarrhea are listed in Table 136-1.

A physical examination and careful history that includes information about symptoms and symptom duration, the number of individuals affected, and recent history of travel, diet, and medications are important factors in making a diagnosis. Infections with norovirus or ETEC will often result in mild, self-limiting disease, whereas cholera will commonly produce severe dehydrating diarrhea. Infections with enteric pathogens such as *Campylobacter* spp., EHEC, *Salmonella* spp., *Shigella* spp., and *Y. enterocolitica* can result in severe symptomatology due to dysentery. The utilization of serum C-reactive protein (CRP) in young adult patients with infectious diarrhea may be able to help differentiate between noninflammatory and inflammatory causes.[26] Assessing CRP could assist with diagnosis, prognosis, and treatment selection. The clinical presentation of acute viral and bacterial gastroenteritis is summarized in Tables 136-2 and 136-3, respectively.

③ Stool culture is an important tool in making an organism-specific diagnosis and determining susceptibility to antimicrobial agents. Due to the low yield, stool cultures are not recommended in most mild-to-moderate watery diarrhea. Instead, indications for stool cultures include dysenteric diarrhea, persistent diarrhea in immunocompromised patients (ie, persons aged 65 years and older with comorbid diseases, neutropenia, or HIV infection), and diarrhea where an outbreak is suggested.[1] An appropriately obtained stool culture identifies the presence of *Campylobacter*, *Salmonella*, and *Shigella* spp. The yield of stool cultures for other pathogens is increased if the test is ordered specifically based on history and physical examination. For dysenteric diarrhea, the laboratory should be instructed to evaluate for EHEC including STEC (*E. coli* O157:H7). In hospitalized patients who develop diarrhea 3 days after hospitalization or in those with recent exposure to antimicrobials or chemotherapy, stool specimen should be sent for *C. difficile* toxins A and B. In addition to stool cultures, microscopic examination for fecal polymorphonuclear cells, or a simple immunoassay for the neutrophil marker lactoferrin, can further provide evidence of an inflammatory process and increase the yield of cultures in patients presenting with dysenteric diarrhea.[1]

Complications

Complications associated with acute diarrhea most likely result from dehydration so treatment focuses primarily on rehydration therapy, regardless of the etiology. Dysenteric diarrhea is more likely to have severe complications, especially in children younger than 5 years and in elderly. Bacteremia is the most common complication of gastroenteritis and can be seen after infections with nontyphoid *Salmonella*, *C. jejuni* or *C. fetus*, and *Y. enterocolitica*.[16] Nontyphoid *Salmonella* is most common in children younger than 5 years, elderly, and patients with hemoglobinopathy, malaria, or immunosuppression. Bacteremia due to *Campylobacter* spp. has been reported in patients with HIV infection, malignancy, transplantation, and hypogammaglobulinemia. *Y. enterocolitica* bacteremia has been rarely reported, but has an increased prevalence in patients with diabetes mellitus, severe anemia, hemochromatosis, iron overload (frequent transfusion), cirrhosis, malignancy, and in the elderly.[27] Persistent bacteremia with these pathogens will commonly result in prolonged intermittent fever with chills. Potentially complicating the diagnosis, stool cultures frequently are negative and leukocyte counts are often within the normal range. Vascular complications such as seeding of atherosclerotic plaques or aneurysms in arterial vessels occur in 10% to 25% of adults with bacteremia. Localized infections involving bone, cysts, heart, kidney, liver, lungs, pericardium, and spleen develop in 5% to 10% of patients with bacteremia.

A severe complication in patients infected with EHEC is HUS. HUS is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia and is more commonly observed in children younger than 5 years and in the elderly.[28] Approximately 2% to 7% of cases infected with STEC strains are complicated by development of HUS, which increases mortality associated with this infection. *S. dysenteriae* type 1 can also cause HUS, although more rarely than observed with EHEC.[18]

Shigella infection may also lead to complications such as generalized seizures, sepsis, toxic megacolon, perforated colon, arthritis, and protein-losing enteropathy. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.[29]

Infection with *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.[30] The risk of developing GBS after *C. jejuni* infection appears to be low (approximately 1 case of GBS per 1,000 *C. jejuni* infections). The weakness associated with GBS usually starts in the legs, with difficulty in walking, and may progress to a complete paralysis of all extremities that lasts several weeks and usually requires intensive care.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from gastroenteritis secondary to *S. flexneri*, *Salmonella* spp., *C. jejuni*, and *Y. enterocolitica*. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.[30] This complication is more common in persons with the HLA-B27 antigen.

A general complication that could occur long after an infectious gastroenteritis, especially with dysentery and toxin-mediated dysentery, is postinfectious irritable bowel syndrome (IBS). This is classified as IBS symptoms for at least 3 months following an episode of gastroenteritis or traveler's diarrhea showing recurrent abdominal pain or discomfort.[31] Albeit rare, some long-term complications associated with these infections strengthen the need for appropriate diagnosis and treatment.

TREATMENT

Mortality associated with infectious diarrhea has declined substantially in the past two decades, especially among children younger than 1 year. Preventative measures including improved sanitation, breast-feeding and weaning practices, and increased use of oral rehydration therapy (ORT) for affected individuals are responsible for the decrease in case-fatality rates.

General Approach to Treatment

The cornerstone of management for all GI infections and enterotoxigenic poisonings is to prevent dehydration by correcting fluid and electrolyte imbalances. In mild, self-limiting acute gastroenteritis, a diet of oral fluids and easily digestible foods is recommended. In patients with severe dehydrating watery diarrhea and dysenteric diarrhea, IV rehydration therapy, antibiotics, and/or antimotility treatments are needed.

Rehydration Therapy

Initial assessment of fluid loss is essential for successful rehydration therapy and should include acute weight loss, as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (Table 136-4). Physical assessment generally is more reliable in young children and infants than in adults.

TABLE 136-4

Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss[a]

Variable	Minimal or No Dehydration (<3% Loss of Body Weight)	Mild-to-Moderate (3%-9% Loss of Body Weight)	Severe (≥10% Loss of Body Weight)
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Weak, thready, or not palpable
Heart rate	Normal	Normal to increased	Increased (bradycardia in severe cases)
Breathing	Normal	Normal to fast	Deep
Mental status	Normal	Normal to listless	Apathetic, lethargic, or comatose
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/absent tears
Mouth and tongue	Moist	Dry	Parched
Thirst	Normal	Eager to drink	Drinks poorly; too lethargic to drink
Skin fold	Normal	Recoil in <2 seconds	Recoil in >2 seconds
Extremities	Warm, normal capillary refill	Cool, prolonged capillary refill	Cold, mottled, cyanotic, prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Hydration therapy	None	ORS 50-100 mL/kg over 3-4 hours	• Lactated Ringer's solution or normal saline 20 mL/kg over 15-30 minutes IV until mental status or perfusion improves • Followed by 5% dextrose/0.45% sodium chloride IV at higher maintenance rates or ORS 100 mL/kg over 4 hours
Replacement of ongoing losses	• For each diarrheal stool or emesis • <10 kg body weight: 60-120 mL ORS • >10 kg body weight: 120-240 mL ORS	Same as minimal dehydration	If unable to tolerate ORS, administer through nasogastric tube or administer 5% dextrose/0.45% sodium chloride with 20 mEq/L (mmol/L) potassium chloride IV

ORS, oral rehydration solution.

[a] Percentages vary among patients for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

③Fluid replacement is the cornerstone of therapy for dehydration due to diarrhea regardless of etiology. For the treatment of mild-to-moderate dehydration, ORT is superior to administration of IV fluids. Oral replacement therapy reverses dehydration in nearly all patients with mild-to-moderate diarrhea with 94% to 97% efficacy.[1] It offers advantages of being inexpensive, noninvasive, and not requiring inpatient administration. Moreover, thirst drives use of ORT and provides a safeguard against overhydration. Replacement of ongoing losses as well as continuation of normal feeding should also be addressed.

The necessary components of oral rehydration solutions (ORS) include carbohydrates (typically glucose), sodium, potassium, chloride, and water. Using both salt and glucose in the ORS takes advantage of glucose-coupled sodium transport in the small bowel and enhances sodium and subsequently water transport across intestinal walls. The World Health Organization/United Nations Children’s Fund (WHO/UNICEF) endorsed a reduced osmolarity solution (osmolarity ≤250 mOsm/L) as the use of these solutions reduced stool volume, shortened duration of diarrhea, and decreased need for unscheduled IV therapy when compared with previously used ORS more than or equal to 310 mOsm/L.[32] The newer formulation of ORS less than or equal to 250 mOsm/L was, however, more likely to cause hyponatremia (blood sodium levels <130 mEq/L [mmol/L]).[33] If commercial ORS are unavailable, one can be roughly duplicated by mixing ½ teaspoon of salt with 6 teaspoons of sugar in 1 L of water.[34]

In restoring fluid and electrolyte balance in cholera infections, polymer-based ORS may be more efficacious than glucose-based ORS. Polymer-based ORS contains rice, wheat, sorghum, or maize. This polymer-based ORS releases glucose more slowly after digestion and, when absorbed in the small bowel, enhances the reabsorption of water and electrolyte secreted into the bowel lumen during diarrhea. Polymer-based ORS reduces the duration of diarrhea in adults with cholera when compared with glucose-based ORS more than or equal to 310 and less than or equal to 270 mOsm/L.[35]

Guidelines for rehydration therapy based on the degree of dehydration and replacement of ongoing losses are outlined in Table 136-4. ORS should be given in small and frequent volumes (5 mL every 2 to 3 minutes in a teaspoon or oral syringe). Nasogastric administration of ORS is an alternative method of administration in a child with persistent vomiting. For breast-fed infants, nursing should be continued. The composition of commercial ORS and commonly consumed beverages is listed in Table 136-5. Clear fluids, such as soft drinks, sweetened fruit drinks, chicken broth, and sports drinks, should be avoided in the treatment of dehydration. These hyperosmolar solutions may cause an osmotic diarrhea.

TABLE 136-5

Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)[b]	K (mEq/L)[b]	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)
WHO/UNICEF (2002)	75	20	30	75	245
Pedialyte	45	20	30	140	250
Infalyte	50	25	30	70	200
Oralyte	60	20	0	90	260
Rehydralyte	75	20	30	140	250
Cola[a]	2	0	13	700	750
Apple juice[a]	5	32	0	690	730
Chicken broth[a]	250	8	0	0	500
Sports beverage[a]	20	3	3	255	330

[a] These solutions should be avoided in dehydration.

[b] Concentration of monovalent ions expressed in mEq/L is numerically equivalent to mmol/L concentration.

In the treatment of severe dehydration, the primary goal of therapy is rapid restoration of fluid losses, correction of metabolic acidosis, and replacement of potassium deficiency. Severely dehydrated patients should be resuscitated initially with IV lactated Ringer solution or normal saline to restore hemodynamic stability. Lactated Ringer solution is preferred initially over normal saline because normal saline does not assist in correcting a metabolic acidosis. As GI and renal perfusion should be addressed aggressively, rapid IV administration is preferred over prolonged administration regimens for restoring extracellular fluids and electrolytes.[36] After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes. ORT should be instituted as soon as it can be tolerated.

Early refeeding with age-appropriate unrestricted diet is recommended in children. Early refeeding during or immediately following the start of rehydration did not increase the risk of complications such as unscheduled IV fluids, vomiting, or development of persistent diarrhea compared with late refeeding that ranged from 20 to 48 hours after start of rehydration.[36] Initially, easily digested foods such as bananas, applesauce, and cereal should be introduced and foods high in fiber, sodium, and sugar should be avoided. One caveat would be that lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

④ The indiscriminate use of antimicrobial therapy produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* spp. worldwide reinforces the importance of judicious use of antibiotics and prudent infection control measures.[37,38] Antibiotic therapy is recommended in severe cases of diarrhea, moderate-to-severe cases of traveler's diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea. Antimicrobial therapy is not recommended in EHEC diarrhea as it may increase HUS risk.

Antibiotic therapy is recommended in severe cases of cholera and ETEC diarrhea. In cases of cholera, antibiotics shorten the duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.[1,12] It is important to consider local susceptibility patterns in the selection of the antimicrobial regimen. In areas of high fluoroquinolone resistance, azithromycin has been effective in patients with cholera. In patients with ETEC diarrhea, empiric antibiotics reduce severity and duration of diarrhea. A short course of therapy with fluoroquinolones is the most commonly recommended therapy due to increased resistance among other drug classes.[39] Rifaximin has been effective for ETEC for travel in Mexico.[40] Further discussions of antibiotic prophylaxis and treatment can be found in the section on traveler's diarrhea. Table 136-6 summarizes antibiotic recommendations. Further details regarding treatment of *C. difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses are discussed in respective sections.

TABLE 136-6

Recommendations for Antibiotic Therapy

Pathogen	Children	Adults
Watery Diarrhea		
Enterotoxigenic *Escherichia coli*	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 1-3 days. Alternatives: rifaximin 200 mg orally three times daily × 3 days; azithromycin 1,000 mg orally × 1 day *or* 500 mg orally daily × 3 days
Vibrio cholerae O1	Erythromycin 30 mg/kg/day divided every 8 hours orally × 3 days; azithromycin 10 mg/kg/day given orally once daily × 3 days	Doxycycline 300 mg orally × 1 day Alternatives: azithromycin 500 mg orally once daily × 3 days; ciprofloxacin 750 mg orally once daily × 3 days; ceftriaxone IV
Dysenteric Diarrhea		
Campylobacter species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3-5 days; erythromycin 30 mg/kg/day divided into two to four doses orally × 3-5 days	Azithromycin 500 mg orally once daily × 3 days Alternatives: ciprofloxacin 750 mg orally once daily × 7 days
Salmonella Nontyphoidal[a]	Ceftriaxone 100 mg/kg/day divided IV every 12 hours × 7-10 days; azithromycin 20 mg/kg/day orally once daily × 7 days	Ceftriaxone 2 g IV/IM once; ciprofloxacin 750 mg orally once daily × 7-10 days; Alternatives: ampicillin 250-500 mg orally every 6 hours × 7 days; azithromycin 500 mg orally once daily × 7 days; Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days For immunocompromised patients, duration should be increased to 14 days for both fluoroquinolones and azithromycin
Shigella species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Azithromycin 500 mg orally once daily x 3 days; ceftriaxone 2 g IV/IM once; ciprofloxacin 750 mg orally once daily × 3 days; Alternatives: ampicillin 250-500 mg orally every 6 hours × 7 days; Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days
Yersinia species[a]	Treat as children with shigellosis	Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days Alternatives: cefotaxime IV or ciprofloxacin 750 mg orally once daily × 7 days
Traveler's Diarrhea		
Prophylaxis[a]		None recommended
Treatment		Azithromycin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days, Ciprofloxacin 750 mg orally × 1 day or 500 mg orally twice daily × 3 days; levofloxacin 500 mg orally daily × 3 days, ofloxacin 400 mg twice daily x 1-3 days, rifamycin SV 388 mg twice daily x 3 days, rifaximin 200 mg three times daily × 3 days

[a] For high-risk patients only. See the preceding text for the high-risk patients in each infection.

Antibiotic therapy is indicated in at-risk and febrile patients with dysenteric diarrhea. In shigellosis, antibiotics shorten the period of fecal shedding and attenuate the clinical illness. Antibiotic therapy is reserved for the elderly, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. In the United States, *Shigella* spp. remain susceptible to fluoroquinolones. Fluoroquinolone resistance among *Shigella* spp. is of increasing concern in developing countries, and azithromycin may be a better choice in patients with a recent history of travel to a developing region.[1,18] Similar antibiotic regimens can be used for high-risk patients who develop *Yersinia* bacteremia (ie, infants younger than 3 months and patients with cirrhosis or iron overload) or in patients with bone and joint infections.[41] With Campylobacteriosis, antibiotics are not useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea and only shorten the duration of bacterial excretion. Antibiotics are warranted in patients with high fevers, severe bloody diarrhea, prolonged illnesses (more than 1 week), pregnancy, and immunocompromised states, including HIV infection. Fluoroquinolone resistance among *Campylobacter* spp. has increased, and is now 10% to 13% in the United States and 41% to 88% in Europe and Asia. Resistance may be the result of the use of fluoroquinolone antibiotics in poultry and other animal feed, and the frequent use of these agents internationally in treating enteric infections. Macrolides like azithromycin are recommended especially in patients with a recent history of travel to Asia.[39]

Nontyphoid *Salmonella* infection leads to bacteremia in approximately 8% of otherwise healthy adults. However, patients with increased risk of bacteremia should be treated with antibiotics if appropriate diagnosis is made. High-risk patients include neonates or infants younger than 1 year, persons older than 50 years, and patients with primary or secondary immunodeficiency such as acquired immunodeficiency syndrome (AIDS) or chemotherapy-induced inflammatory bowel disease, sickle cell disease, vascular abnormalities (prostatic heart valve or abdominal aneurysm), or prosthetic joints.[18] If cultures are positive for Salmonellosis and antibacterial therapy is warranted, susceptibility testing should be done for appropriate targeted therapy due to concern of resistance. *Salmonella enterica* serotype Typhi can cause enterocolitis and is a risk for typhoid fever. Although this pathogen is less prevalent, recent data have shown extensive drug resistance (susceptible to carbapenem or macrolide only), especially when travel to certain areas of the world (eg, Pakistan) were involved.[42] When treatment is required, it is important to take a full patient history to see if a patient may have a drug-resistant pathogen as the causative agent.

Outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibacterials, therefore precluding their use. In patients infected with EHEC, use of a fluoroquinolone or trimethoprim-sulfamethoxazole may increase the risk of HUS by increasing the production of Shiga-like toxin.[1,41] Empiric antimicrobial therapy should be withheld when clinical suspicion is high due to the high local prevalence EHEC, patient clinical presentation suggestive of EHEC infection, or a known foodborne outbreak of dysentery with an incubation period of longer than 2 days. Antibiotics should not be given to infants or children due to a higher incidence of HUS in this population. Treatment of EHEC infection is primarily limited to supportive care, which may include fluid replacement therapy, hemodialysis, hemofiltration, transfusion red blood cells and/or platelets, and other interventions as indicated clinically. Severe disease may lead to chronic kidney failure and potential need of renal transplantation.

Antimotility Agents

⑤ Antimotility drugs such as diphenoxylate/atropine and loperamide offer symptomatic relief in patients with watery diarrhea by reducing the number of stools. However, in both enterotoxigenic and dysenteric diarrhea, slowing of fecal transit time with these agents is thought to result in extended toxin-associated damage, worsening symptomatology and leads to complications. Therefore, antimotility drugs should be avoided if possible and are not recommended in patients with toxin-mediated dysenteric diarrhea (ie, EHEC, pseudomembranous colitis, shigellosis). However, some evidence suggests that in adults with dysenteric diarrhea these agents do not appear to be harmful if given concomitantly with antibacterial therapy.[41]

Probiotics

Probiotics are preparations of microorganisms and most commercial products have been derived from food sources, particularly cultured milk products (ie, lactobacilli and bifidobacteria). When used in the treatment or prophylaxis of infectious diarrhea and antibiotic-associated diarrhea, efficacy is variable. Most individual studies have not shown significant benefit from the use of probiotics and meta-analyses have shown conflicting results, with one demonstrating efficacy when trials were assessed in aggregate[43] and another demonstrating no benefit.[44] Significantly decreased rates of CDI followed lactobacillus use in patients receiving 2 or more days of systemic antibacterials.[45] No serious adverse effects have been reported in otherwise healthy persons; however, there are data suggesting a rare but increased incidence of fungemia or bacterial sepsis with probiotic use. With confounding data both supporting and refuting the use of probiotics for prevention, the decision should be based upon patient-specific criteria.

Oral Zinc Supplementation

Zinc deficiency is largely due to inadequate dietary intake and is common in many developing countries where morbidity and mortality associated with acute diarrhea in children remains high. In children older than 6 months who demonstrate moderate signs of malnutrition, zinc supplementation may shorten the duration of diarrhea by approximately 27 hours (95% CI −14.62 to −39.34).[46] Therefore, oral zinc supplementation of 20 mg/day for 1 to 2 weeks may have an additional benefit over ORS alone in reducing childhood mortality in developing countries. Common side effects include metallic taste and vomiting. At high doses, zinc supplementation may cause epigastric pain, lethargy, and fatigue.

PREVENTION OF GASTROINTESTINAL INFECTIONS

⑥ Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of GI infections. In addition, following simple rules of personal hygiene and safe food preparation can prevent many diarrheal diseases. Hand washing with soap and running water is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital to investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine (ViCPS) and the oral live-attenuated Ty21a vaccine.[47] Efficacy rates for both vaccines range from 50% to 80%. The ViCPS is indicated for children who are 2 years of age or older, and a booster dose is administered 2 years after the first. The Ty21a vaccine is indicated for children 6 years or older; one capsule should be swallowed whole every other day for a total of four doses at least 1 week before the potential exposure. A booster should be taken every 5 years if continued protection is needed.

In the United States, routine rotavirus vaccination is recommended for all infants beginning at age 2 months. There are two vaccines, RotaTeq (RV5) and Rotarix (RV1), available for reducing rotaviral gastroenteritis.[48] The RV5 vaccine is a live, oral vaccine that offers 74% efficacy against gastroenteritis of any severity and 98% efficacy against severe disease. This vaccine also decreased office visits by 86%, emergency department visits by 94%, and hospitalizations by 96%. The RV1 vaccine is a live-attenuated human rotavirus vaccine. This vaccine has clinical efficacy of 79% against gastroenteritis of any severity and 96% efficacy against severe rotavirus disease. Rotarix reduced hospitalizations by 100% and medically attended visits by 92% in the first rotavirus season, and reduced hospitalizations by 96% through two seasons.[48] The RV5 vaccine is administered orally in a three-dose series at ages 2, 4, and 6 months while the RV1 vaccine is administered orally in a two-dose series at ages 2 and 4 months. The first dose may be given between 6 weeks and 14 weeks and 6 days of age and all doses should be given before 8 months of age. The vaccines are contraindicated in infants with severe allergic reactions to vaccine components, diagnosed with severe combined immunodeficiency, and with history of intussusception.[49]

Although not available in the United States, two oral vaccines against diarrheal pathogens are available in other countries. Dukoral consists of killed *V. cholerae* O1 organisms and the cholera B subunit, and is licensed in over 60 countries. Shanchol consists of killed whole cells from a mix of pathogenic strains of *V. cholerae* (O1 and O139) and is licensed in India.[11,13] Both vaccines are given in two doses (three doses of Dukoral are required for children aged 2-5 years) and administered about 7 to 14 days apart (up to 42 days apart for Dukoral). Dukoral must be administered with a buffer that requires 75 to 150 mL of clean water while Shanchol does not require the buffer. Both vaccines demonstrated protective efficacy of 47% to 87% after two doses but almost none after a single dose. Protection is achieved in approximately 1 week following the last dose and persists for approximately 2 years. The common side effects of the vaccines were considered mild and included abdominal pain, headache, fever, and nausea. The WHO does not require vaccination for international travel to or from endemic areas because vaccines require two doses and provide incomplete protection for a relatively short period of time.[13]

There are vaccines in development for common enteric pathogens including ETEC and *Shigella* spp. with the potential for combining them in a single vaccine. These are still in preliminary and animal-based studies, but could significantly affect global public health if they come to fruition for human administration, especially in the infants and children.[50]

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms that lead to the diagnosis also can assess adequate rehydration, and should be monitored frequently. With ORT preferred, routine laboratory testing often is unnecessary. Electrolytes should be measured in those receiving IV fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. Prompt discharge of hospitalized patients is recommended when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

CLOSTRIDIOIDES DIFFICILE

Epidemiology

C. difficile is the most commonly recognized cause of infectious diarrhea in healthcare settings with high rates of disease in the elderly and those exposed to antibiotic agents. While almost all antibiotics have been implicated in *C. difficile* infection (CDI), those most commonly associated include fluoroquinolones, clindamycin, carbapenems, and third-/fourth-generation cephalosporins. CDI often occurs during or shortly after completion of antimicrobial therapy; however, disease onset can be delayed for 3 or more months.[51] Other risk factors for acquisition of *C. difficile* include recent healthcare exposure, chemotherapy, patients undergoing gastrointestinal surgery or receiving tube feeding, and potentially those receiving acid suppressive medications. While some studies show an association between *CDI* and acid suppressing medications, such as proton pump inhibitors (PPIs) and histamine-2 blockers, there is variability in the literature and a need for prospective randomized trials to confirm this link.[51,52]

Incidence of CDI was steadily rising in the early 2000s, appearing to peak around 2010 at approximately 500,000 cases annually in the United States and Europe. Growing concern for CDI, especially in the healthcare facilities, led to the creation of the Centers for Disease Control and Prevention (CDC) Emerging Infection Program (EIP) CDI tracking program. This program has been conducting population-based surveillance of *C. difficile* in 10 US cities since 2011 in order to estimate the national burden of CDI. While the epidemiology of CDI has remained relatively steady, trends indicate a decline in healthcare associated infecitons.[51,53] One confounding factor in the estimation of CDI incidence is the introduction of more sensitive tests, such as nucleic acid amplification tests (NAATs), which may lead to overdiagnosis.[53] Recurrent CDI is a major problem, with escalating risk of infection and increased mortality with subsequent infections.[51,52]

Etiology and Pathophysiology

C. difficile is a gram-positive spore-forming obligate anaerobic bacterium that may colonize the large intestine of healthy individuals, as well as those experiencing a symptomatic CDI. *C. difficile* is transmitted most commonly by the fecal-oral route through ingestion of *C. difficile* spores. Pathogenic CDI occurs when there is disruption of the bowel flora and/or an inadequate immune response. Two major toxins (toxin A [TcdA] and toxin B [TcdB]) are released and lead to a loss of integrity of colonic epithelial cells.[54] This mediates an inflammatory cascade that causes tissue damage and results in diarrhea. Initially, raised white and yellowish plaques form in the colon and the surrounding mucosa may become inflamed. With progression of disease, pseudomembranous plaques become enlarged and scattered over the colorectal mucosa resulting in pseudomembranous colitis.[51] The production of binary toxin, mutations causing hyperproduction of toxins, antibiotic resistance, increased sporulation, and mutations that increase adherence to the intestinal epithelium may contribute to the virulence and disease severity in the host. Some strains, such BI/NAP1/027, express multiple mutations that make it hypervirulent and are a cause of significant clinical concern.[54]

CLINICAL PRESENTATION

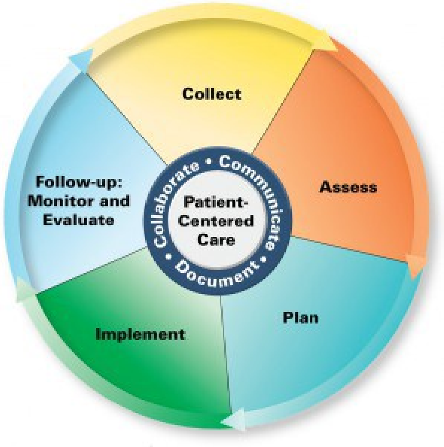
Symptoms of CDI range from mild diarrhea to fulminant disease and toxic megacolon. The diarrhea is typically watery and nonbloody, and is often associated with abdominal discomfort, fever, and leukocytosis. Patients with new and unexplained diarrhea (>3 unformed stools in 24 hours) should be evaluated for CDI.

Diagnosis of CDI is confirmed by identification of *C. difficile* organisms/toxin in stool or by colonoscopic or histopathologic findings revealing pseudomembranous colitis.[51]

The optimal test for laboratory diagnosis remains controversial. Nucleic acid amplification tests (NAAT), such as PCR-based toxin testing, are very popular in the United States and have high sensitivity and specificity; however, they should only be used in patients with acute diarrhea due to the possibility of detecting the toxins in asymptomatic patients.[51,52] Alternatively, a stepwise approach uses screening for glutamate dehydrogenase (GDH) as the initial step. GDH assays detect a common antigen present in all isolates of *C. difficile*, including nontoxigenic strains, thus requiring combination with another test (typically a toxin test with or without NAAT). The stepwise approach may be preferred in institutions where there is no criteria for stool submission in order to minimize the false positive results that may result with NAAT alone. Utility of toxigenic culture or cell culture neutralization assays are limited due to delayed results and high cost. Use of toxin enzyme immunoassay (EIA) alone has a low sensitivity and has largely been replaced by NAAT testing or incorporated into multistep algorithms along with GDH assays.[51,55]

PATIENT CARE PROCESS

Patient Care Process for *Clostridioides difficile* Infections (CDI)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (personal and family), including any previous episodes of CDI
- Social history (eg, tobacco/ethanol use) and dietary habits
- Current medications including OTC, herbal products, dietary supplements, acid suppressive medication, and previous antibiotic use (within the past 3 months)
- Characteristics of diarrhea including onset, number of episodes per day, and presence of blood
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
    - Labs including white blood cell count (WBC) and serum creatinine (SCr)
    - Stool sample to be tested for *C. difficile* toxins
    - Radiographic abdominal imaging if concern for ileus or megacolon

Assess

- Hemodynamic stability (eg, systolic BP <90 mm Hg, HR >110 bpm, O_2-sat <90% [0.90], RR)
- Radiographic studies for the presence of ileus, megacolon, or perforation
- Presence of CDI risk factors (age, antibiotic use, recent healthcare exposure, chemotherapy, GI surgery, tube feeding, acid suppressive medications)
- Ability to stop offending antibiotic agent if applicable
- Ability/willingness to pay for first-line treatment options
- Ability/willingness to try investigational therapies such as fecal microbiota transplant (if applicable for recurrent disease)
- Ability/willingness to pay for adjunctive therapy with bezlotoxumab

Plan*

- Drug therapy regimen including specific antibiotic dose, route, frequency, and duration (see Table 136-7)
- Discontinuation of offending antibiotic agent if applicable
- Monitoring parameters, such as resolution of diarrhea; frequency and timing of follow-up
- Patient education (eg, purpose of treatment, drug-specific information, and prevention of disease transmission)
- Self-monitoring for resolution of diarrhea and when to seek emergency medical att ention
- Referrals to other providers when appropriate (eg, infectious diseases, gasteroenterology)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Resolution of diarrhea
- Presence of adverse effects (eg, CNS effects, metallic taste if metronidazole used; nausea, abdominal pain)
- Patient adherence to treatment plan using multiple sources of information
- Educate on limiting risk factors, such as antibiotic agents and acid suppressive medications

**Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 136-7

Clostridioides difficile **Infection Severity and Treatment**

Severity	**Markers of Disease Severity**	**Recommended Treatment**
Nonsevere	WBC ≤15,000 cells/mm^3 (15 × 10^9/L) SCr <1.5 mg/dL (133 μmol/L)	Vancomycin 125 mg orally four times daily for 10 days, OR Fidaxomicin[a] 200 mg orally twice daily for 10 days, OR Metronidazole[b] 500 mg orally every 8 hours for 10 days.
Severe	- WBC >15,000 cells/mm^3 (15 × 10^9/L) - SCr >1.5 mg/dL (133 μmol/L)	Vancomycin 125 mg orally four times daily for 10 days, OR Fidaxomicin 200 mg orally twice daily for 10 days
Fulminant	- Hypotension or shock - Ileus and/or megacolon	Metronidazole 500 mg IV every 8 hours *PLUS* vancomycin 500 mg every 6 hours via NG or orally (if ileus present use rectally)

[a] Fidaxomicin is preferred over vancomycin for patients with an initial CDI per IDSA/SHEA 2021 Focused Update.

[b] Metronidazole is an alternative therapy if other agents are unavailable or too costly.

Data from References 51,56.

NG, nasogastric; SCr, serum creatinine; WBC, white blood cell.

Treatment

Supportive care of CDI includes fluid and electrolyte replacement therapy, in addition to discontinuation of the offending antimicrobial if possible. Antimotility agents (such as diphenoxylate/atropine and loperamide) and exchange resins (such as cholestyramine and colestipol) have been used in CDI; however, in general their use is discouraged. Empiric therapy for CDI may be considered if the patient has a strong pre-test suspicion for CDI and is severely ill, or if there is an expected substantial delay in laboratory confirmation. Antibiotic therapy is based on disease severity and may vary for first episode or recurrent infection.[51] Table 136-7 outlines CDI disease severity and treatment regimens for initial episodes according to the IDSA/SHEA 2017 clinical practice guidelines. Differences exist among the available guidelines with regard to the definitions of nonsevere, severe, and fulminant or complicated CDI and slight treatment differences. There is a need for prospectively validated severity scores for patients with CDI.

⑦ In the United States, vancomycin and fidaxomicin are FDA approved for CDI. These treatments are well tolerated because they have minimal systemic absorption when administered orally; the main adverse effects are nausea and abdominal pain. The recommended treatment course is 10 days and repeat stool testing is not recommended as a test of cure.[51] For nearly three decades oral metronidazole was the drug of choice for mild-to-moderate CDI; however, it has fallen out of favor based on evidence showing it is significantly less effective than vancomycin or fidaxomicin. The IDSA/SHEA 2017 clinical practice guidelines recommended therapies for both nonsevere and severe CDI include oral vancomycin or fidaxomicin. However, based on emerging data demonstrating the sustained response and safety profile of fidaxomicin, it is now the preferred therapy for initial CDI episodes. Vancomycin represents an acceptable alternative if fidaxomicin is not available, which may be reasonable based on the cost and variable medical insurance coverage of fidaxomicin.[56] When used for CDI, vancomycin must be administered orally because IV vancomycin does not achieve adequate gut lumen concentrations for effective bacterial elimination. Vancomycin is available as a capsule and there are several reconstituted oral solution or suspensions commercially available. The IV formulation has also been compounded and administered orally as a cost-effective option.

In patients with severe/complicated or fulminant CDI the preferred regimen is combination therapy with IV metronidazole and vancomycin.[57] The route of vancomycin administration is patient-dependent; oral is preferred, but if ileus is present, rectal administration via retention enema is recommended at a dose of 500 mg in 100 mL of saline administered four times daily. Fidaxomicin has not been studied in complicated or fulminant disease, therefore is not recommended.[51] Some patients with fulminant disease may require surgical intervention with procedures such as diverting loop ileostomy or total colectomy.

Recurrent CDI (rCDI) is typically defined as an episode of CDI within 8 weeks from the previous episode. Approximately 15% to 35% of patients will have a recurrence and the rate nearly doubles after two or more recurrences.[58] Risk factors for recurrent CDI include increasing age, use of additional antimicrobials, gastric acid suppression, hypervirulent strains, and low antibody response to *C. difficile* toxins.[51,58] The preferred regimen for the first episode of rCDI is fidaxomicin standard dose or an extended-pulsed regimen (200 mg twice daily for 5 days, then once every other day for 20 days). Pulsed and tapered oral vancomycin is an alternative approach for the first recurrence. If metronidazole was used initially, then a standard vancomycin course can be utilized for the first recurrence. For patients with multiple recurrences fidaxomicin remains the preferred agent; however, pulsed/tapered vancomycin, vancomycin followed by rifaximin, or fecal microbiota transplantation (FMT) are acceptable alternatives.[56]

The importance of the gut microbiome and its relationship to primary and recurrent CDI has led to research on several emerging therapies for CDI. Multiple randomized controlled trials have shown efficacy of FMT with resolution rates up to 90%. The American College of Gastroenterology recommends FMT by colonoscopy or capsule formulation oral ingestion with rCDI.[58,59] Protocols that have been studied include stool suspension administered to the lower bowel (through colonoscopy, rectal tube, or enema) or the upper GI tract (through nasogastric or duodenal tube or gastroscope). Several microbiota products available in a capsule formulation are undergoing clinical trials and may be available for use in the near future.[6,60]

A monoclonal antibody, bezlotoxumab, that binds to and neutralizes toxin B is FDA approved as an adjunctive therapy to reduce the recurrence of CDI. The approved dose is 10 mg/kg IV as a single dose during antibacterial treatment for CDI. Bezlotoxumab is not an antibiotic and should not be used as monotherapy. For patients with rCDI within 6 months, IDSA/SHEA suggest bezlotoxumab use during the administration of standard of care antibiotics. There may be feasibility concerns, such as cost and logistics, with this approach. The benefit of adding bezlotoxumab to fidaxomicin is unknown at this time due to limited data with concurrent use of these agents.[56] While generally well tolerated, adverse effects were greater in patients with heart failure who were treated with bezlotoxumab; use in these patients should be considered carefully.[61]

Growing concern for CDI has led to an influx of new antibiotics targeting *C. difficile*. A common characteristic of many of the emerging therapies for CDI is a narrow spectrum of activity with the aim to minimize gut dysbiosis. As many of these agents complete phase III trials, it may change the treatment landscape for CDI in the future.[62]

Prevention of CDI involves both preventing the acquisition of the infection and stopping transmission of *C. difficile* spores to other patients. CDI has become the focus of antimicrobial stewardship efforts aimed at eliminating unnecessary antibiotics and reducing durations of therapy, which may be responsible for the plateau of CDI rates in recent years. The use of probiotics to prevent CDI remains controversial.[60,63]Some studies and meta-analyses have shown no benefit, while other evidence supports probiotic safety and efficacy in preventing CDI. Currently, there is insufficient evidence to recommend probiotics and they are not recommended by the American College of Gastroenterology.[1,51] Hand washing and contact precautions are imperative measures in preventing the spread of the organism. Alcohol is less effective at eliminating *C. difficile* spores compared to use of soap and water; however, there is no association between alcohol-based hand hygiene and increased CDI incidence. Nonetheless, the use of soap and water to prevent disease transmission is the preferred strategy. Proper environmental disinfecting measures in healthcare settings include use of sporicidal cleaning agents.[51,60,61,63]

TRAVELER’S DIARRHEA

Traveler’s diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers. It interferes with planned activities or work in 30% of those affected. In particular, an increased risk lies with North Americans and Northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, inflammatory bowel disease, and people with chronic debilitating medical conditions. Overall, 30% to 70% of people traveling to high-risk areas will develop the illness.[39]

⑧The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home. Traveler's diarrhea is caused by contaminated food or water. The most common pathogens are bacterial and include ETEC, *Campylobacter* spp., *Shigella* spp., and *Salmonella* spp.[10] Viral causes occur in less than 10% of cases with 80% to 90% of cases resulting from bacterial etiologies.[39] Enterotoxigenic *E. coli* is predominantly pathogenic in Latin America, Africa, and South Asia. The invasive enteric pathogens (*Campylobacter* spp., *Salmonella* spp., and *Shigella* spp.) are more important causes of traveler's diarrhea in Asia.

The severity of the syndrome is determined by the number of stools per day and the presence of cramping, nausea, and vomiting. Mild diarrhea is defined as one to three loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than four loose stools daily associated with dehydration, and severe diarrhea is defined as the presence of blood in stools or a fever. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in several days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, antibiotics (3-day course) (see "Treatment" section below), ORS salts, and a water purification method.[39]

Prevention

⑨Patient education in avoiding high-risk food and beverages should be the best method for minimizing the risk. High-risk foods and beverages include raw or undercooked meat and seafood, moist foods served at room temperature, fruits that cannot be peeled, vegetables, milk from a questionable source, hot sauces on the table, tap water, unsealed bottled water, iced drinks, and food from street vendors. Although education is readily available, the incidence of diarrhea was similar in travelers who followed advice and those who engaged in riskier eating habits.[64] Rationales for this include that cooking foods does not always kill pathogens and food should not be considered safe unless it is cooked until steaming hot. Nonetheless, advisement of avoidance measures regarding safe foods, beverages, and eating establishments is recommended to heighten awareness.

Bismuth subsalicylate 524 mg (two chewable tablets or 2 ounces) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.[39] Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although the efficacy of prophylactic antibiotics has been documented, their use is not recommended for most travelers due to the potential side effects of antibiotics (eg, photosensitivity), predisposition to other infections such as CDI or vaginal candidiasis, the increased risk of selection of drug-resistant organisms, cost, lack of data on the safety and efficacy of antibiotics given for more than 2 or 3 weeks, and availability of rapidly effective antibiotics for treatment. Prophylactic antibiotics are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission. A fluoroquinolone is the drug of choice when traveling to most areas of the world.[39] Due to fluoroquinolone resistance among *Campylobacter* spp., azithromycin can be considered when traveling to South and Southeast Asia.

Rifaximin is a nonabsorbed oral rifamycin that has activity against enteric pathogens and may have a role in the prevention of traveler's diarrhea in select populations. Rrifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% for each of the three dosing regimens compared with placebo.[40] Since rifaximin is effective against traveler's diarrhea due to noninvasive strains of *E. coli*, this agent should be reserved for travel regions where *E. coli* predominates, such as Latin America and Africa. Rifaximin has a tolerability and safety profile comparable to that of placebo. The concern with the class rifamycin is the emergence of resistance when used as monotherapy.

Treatment

The goals of treatment are to avoid dehydration, reduce the severity and duration of symptoms, and prevent interruption of planned activities. Fluid and electrolyte replacement should be initiated at the onset of diarrhea. ORT is generally not required in otherwise healthy individuals; flavored mineral water offers a good source of sodium and glucose. In infants and young children, elderly, and those with chronic debilitating medical conditions, ORT is recommended. For symptom relief, loperamide is preferred because of its quicker onset and longer duration of relief relative to bismuth. Standard dosing of loperamide is 4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and fever. Loperamide should be discontinued if symptoms persist for more than 48 hours. Other symptomatic therapy in mild diarrhea includes bismuth subsalicylate 524 mg every 30 minutes for up to eight doses.[39] As previously discussed, there is insufficient evidence to warrant the recommendation of probiotics.

Since behavioral modification has limited efficacy and chemoprophylaxis is not recommended in most travelers, the current recommendation relies on self-treatment. A single dose of antibiotic and up to 3 days of treatment will improve the condition within 24 to 36 hours, shortening the duration of diarrhea by 1 to 2 days.[39] A single dose of fluoroquinolone is recommended initially and if diarrhea is improved within 12 to 24 hours, antibiotics should be discontinued. Otherwise, it can be continued for up to 3 days. A fluoroquinolone is recommended when traveling to most areas of the world. Where fluoroquinolone-resistant *Campylobacter* is common, such as in South and Southeast Asia, azithromycin should be used.[39] Azithromycin can also be used in pregnant women and children younger than age 16 years. Empiric treatment of young children should be instituted with caution.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler's diarrhea. However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, a 3-day course of rifaximin has been approved for the treatment of traveler's diarrhea caused by noninvasive strains of *E. coli* in people 12 years or older and can be considered when traveling to areas where *E. coli*–associated traveler's diarrhea is common, such as Mexico and Jamaica.[39]

For rapid improvement in symptoms, antibiotic therapy with adjunctive treatment with loperamide has shown benefit.[65] All clinical trials concluded that the combination therapy was safe, and the worsening of the disease with the use of antimotility treatment has not been encountered.

FOOD POISONING

⑩ Foodborne illnesses result from the ingestion of food containing pathogenic microorganisms that cause GI infections or preformed toxins that were produced by microorganisms that cause enterotoxigenic poisonings. In the United States, foodborne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.[4] Foodborne transmission may account for up to 80% of acute gastroenteritis. However, the incidence and outbreaks of foodborne illness have declined in recent years.[66] Common enteric pathogens responsible for foodborne diseases have been discussed in the previous sections (*Campylobacter* spp., *E. coli*, norovirus, nontyphoidal *Salmonella*, *Shigella*). Common foodborne pathogens that cause enterotoxigenic poisonings include *Bacillus cereus*, *Clostridioides botulinum, Clostridioides perfringens*, and *Staphylococcus aureus*. Characteristics of pathogens responsible for foodborne illnesses are summarized in Table 136-8.

TABLE 136-8

Food Poisonings

Organism	Principal Foods	Peak Incidence (United States)	Time to Symptoms	Duration	Common Symptoms
Enterotoxigenic Poisonings					
Bacillus cereus	Fried rice, dairy products, spices, bean sprouts, vegetables	None	1-6 hours 6-24 hours	1 day 1 day	Nausea, vomiting Diarrhea
Clostridioides botulinum	Home-canned fruits, vegetables, meats, honey	None	18-36 hours		Double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness
Clostridioides perfringens (type A)	Meats, poultry, gravies, dried or precooked foods	Fall, winter, spring	8-12 hours	1 day	Abdominal cramps, diarrhea
Staphylococcus aureus	Salad, pastries, ham, sandwiches, puddings, unpasteurized milk, cheese products	Summer	1-6 hours	1 day	Nausea, vomiting, abdominal cramps, diarrhea
GI Infections					
Campylobacter spp.	Poultry, dairy products, clams, water	Spring, summer	2-5 days	7 days	Diarrhea (may be bloody), cramping, abdominal pain, fever
Enteropathogenic *E. coli*	Water	None	1-3 days	5-7 days	Severe diarrhea, vomiting, dehydration
Enterotoxigenic *E. coli*	Water, ice, food	None	1-3 days	3-4 days	Profuse watery diarrhea, abdominal cramping
Salmonella spp.	Beef, poultry, water, eggs, dairy products	Summer	12-72 hours	4-7 days	Diarrhea (sometimes bloody), fever, abdominal cramps
Shigella spp.	Salad, water	Summer	1-2 days	5-7 days	Diarrhea (often bloody), fever, abdominal cramps
Vibrio cholerae	Water	None	2 hours to 5 days	2-3 days	Profuse watery diarrhea, vomiting, leg cramps
Vibrio parahemolyticus	Shellfish (oysters)	Spring, summer, fall	24 hours	3 days	Watery diarrhea, abdominal cramping, nausea, vomiting, fever, chills
Yersinia enterocolitica	Dairy products, raw or undercooked pork products	None	4-7 days	1-3 weeks	Fever, abdominal pain, diarrhea (often bloody)

Because foodborne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute GI or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, and medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Enterotoxigenic poisonings result from ingestion of food contaminated by preformed toxins. Therefore, symptoms are rapid in onset, but most cases of food poisoning are of short duration with recovery occurring within 1 to 2 days. *B. cereus* causes two different types of clinical syndromes. The first one is characterized by a short incubation period and vomiting. The second syndrome has a longer incubation period and is characterized by diarrhea. Foodborne *C. perfringens* infection may present as two distinct syndromes. Type A organisms are seen in Western Hemisphere nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. They can produce a toxin-related syndrome called *enteritis necroticans*, which is a coagulative transmural necrosis of the intestinal wall.[67] This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Foodborne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. Poisoning from *C. botulinum* is rare; only 110 cases are reported per year in the United States. Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins prevent the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias. Foodborne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Diagnosis is made by culturing *C. botulinum* from the stool. The clinical presentation may resemble GBS associated with *C. jejuni* infection. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*–associated GBS.

Treatment consists primarily of respiratory support and use of botulinum antitoxin. If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In foodborne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and IV fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antimotility agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the foodborne illnesses can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

SELF-ASSESSMENT QUESTIONS

1. The most common cause of infectious diarrhea in American children is which of the following pathogens?

   A. *Vibrio cholerae*

   B. *Campylobacter jejuni*

   C. *Yersinia enterocolitica*

   D. *Escherichia coli*

   E. Rotavirus

2. Which of the following pathogens is most commonly associated with dysentery (bloody) diarrhea?

   A. *Vibrio cholerae*

   B. *Escherichia coli*

   C. *Clostridioides difficile*

   D. *Yersinia enterocolitica*

3. Which of the following statements regarding the treatment of *E. coli*–related infectious diarrhea is FALSE?

   A. Initial treatment should include appropriate hydration with low-osmolar or isotonic fluid replacement.

   B. The use of antimotility agents, like loperamide, could potentially increase diarrheal symptoms due to prolonged exposure to bacterial toxin.

   C. Using fluoroquinolone agents for treatment of this infection is appropriate when bloody stools are present and serotype is undetermined.

   D. None of the above are FALSE.

4. Which of the following causes of dysentery diarrhea currently has an available vaccine in the United States that may prevent some species of the disease?

   A. Shigellosis

   B. Campylobacteriosis

   C. Salmonellosis

   D. Yersiniosis

   E. None of the above have available vaccine

5. Which of the following statements regarding rehydration therapy in a patient with gastroenteritis is FALSE?

   A. Intravenous fluid replacement is indicated in all pediatric patients with infectious diarrhea.

   B. Glucose and other simple sugars in high concentrations can worsen diarrhea in a patient acutely ill with gastroenteritis.

   C. If a patient presents with gastroenteritis and an ileus, intravenous fluid replacement is indicated.

   D. None of the above are FALSE.

6. Which of the following statements regarding diagnosis of *Clostridium difficile* infection (CDI) is/are TRUE?

   A. Diagnosis of CDI requires presence of bacterial-released toxin and a host response to that toxin.

   B. Testing for toxin production in CDI with solid, formed stools is appropriate to ensure eradication of the organism.

   C. CDI diagnosis requires anaerobic cultures for confirmation.

   D. All of the above are true.

7. According to current guidelines, what class of antimicrobials would be indicated for treatment in a 62-year-old patient with confirmed enterocolitis due to a *Salmonella* species?

   A. Cephalosporin

   B. Aminoglycoside

   C. Macrolide

   D. Carbapenem

8. Treatment for an adult with campylobacteriosis that started having bloody diarrhea 2 days ago should be initiated on which of the following medication?

   A. Ciprofloxacin

   B. Doxycycline

   C. Metronidazole

   D. Azithromycin

   E. No antimicrobial therapy is warranted

9. Which of the following viral causes of infectious gastroenteritis could be seen during the winter months and would be common in adults?

   A. Rotavirus

   B. Norovirus

   C. Astrovirus

   D. Coronavirus

10. A patient is diagnosed with CDI and has a WBC of 17,500 cells/mm^3 (17.5 x 10^9/L). Which of the following regimens would be an appropriate selection for treatment, according to the most recent guidelines for the treatment of CDI?

    A. Metronidazole 500 mg orally every 8 hours

    B. Vancomycin 125 mg orally every 6 hours

    C. Fidaxomicin 200 mg orally twice daily

    D. All of the above are appropriate

    E. Only TWO of the above are appropriate

11. According to current guidelines, a patient diagnosed with first-episode CDI that is determined to be critically ill (has systemic symptoms including hypotension) should be treated with which of the following for *C. difficile* treatment?

    A. Metronidazole orally

    B. Vancomycin orally

    C. Vancomycin intravenously

    D. Fidaxomicin orally

   E. Metronidazole intravenously + vancomycin orally

12. Which of the following statements is/are TRUE regarding CDI prevention?

   A. Hand washing with soap and water can help prevent person-to-person transmission of CDI.

   B. Room disinfection after a CDI patient is discharged must be performed with alcohol-based cleaners.

   C. *C. difficile* spores survive only hours outside the host, so time is another method of preventing CDI transmission.

   D. Respiratory precautions (masks and face shields) should be utilized when entering and taking care of a CDI patient.

   E. None of the above are true.

13. Which of the following would NOT be considered a common pathogen in causing traveler's diarrhea?

   A. Enterotoxigenic *Escherichia coli*

   B. Rotavirus

   C. *Shigella dysenteriae*

   D. *Vibrio cholerae*

   E. All of the above are common pathogens in traveler's diarrhea

14. Recommended prophylaxis for traveler's diarrhea should include which of the following?

   A. Education on proper food and personal hygiene

   B. Famotidine 20 mg orally twice daily while traveling

   C. Ciprofloxacin 750 mg orally once daily while traveling

   D. All of the above should be recommended

15. A patient is having some diarrhea and is diagnosed with food poisoning following eating potato salad and tapioca pudding at his family reunion. In all likelihood, the causative pathogen is *Staphylococcus aureus*. Which of the following antibacterials should be recommended for his treatment in combination with ORT?

   A. Ciprofloxacin

   B. Azithromycin

   C. Trimethoprim-sulfamethoxazole

   D. Linezolid

   E. No antibiotic therapy is warranted

SELF-ASSESSMENT QUESTION-ANSWERS

1. **E.** Diarrhea is a common malady in children, although more problematic in the developing world. In the United States, the most common pathogen is still viral pathogens so rotavirus is the most likely cause.

2. **D.** Dysentery diarrhea needs to be distinguished from enterotoxigenic (watery) diarrhea based on symptoms and pathogens. Although some pathogens may produce similar symptoms after prolonged illness, *Yersinia* spp. causes dysentery type diarrhea more commonly whereas the other

options are most commonly causes of enterotoxigenic diarrhea.

3. **C.** If only the pathogen is known and the serotype is not, we could precipitate hemolytic uremic syndrome if the serotype is E. coli O157:H7. Preference would be to avoid antimicrobials, if possible, or obtain serotype testing prior to initiating antimicrobial therapy with fluoroquinolones or any potential agent.

4. **C.** The only bacterial pathogen causing gastrointestinal infections that would have an available vaccine is *Salmonella* spp.

5. **C.** Fluid replacement therapy should be instituted for all patients with infectious diarrhea. However, intravenous therapy is not required in pediatric or adult patients unless certain severity criteria are met. The other statements are true.

6. **A.** Diagnosis of *C. difficile* infections require symptoms and a positive toxin test. Cultures are not recommended and solid stools should never be tested for *C. difficile*.

7. **A.** Treatment strategies for salmonellosis include ceftriaxone, ciprofloxacin, or ofloxacin. Of these options, ceftriaxone is a cephalosporin and the fluoroquinolones are not listed as an option. Recall there could be utility of other agents based on resistance profiles, but generally using ceftriaxone should be sufficient.

8. **A.** Because the patient is showing signs of dysentery diarrhea, antimicrobial therapy is often recommended for campylobacteriosis. Here the preferred agent is a macrolide and azithromycin would be the preferred option.

9. **D.** Although common causes of gastroenteritis in the pediatric population, viral causes are less common in adults. Of the choices, norovirus would be predominant in the adult population during winter months, if not bacterial. The other viruses are uncommon in adults.

10. **B.** Treatment for CDI is based upon symptoms and with this patient showing severe etiology, based upon the treatment guidelines, metronidazole should be avoided here and in general for treatment of *C. difficile*. Oral vancomycin or fidaxomicin is the recommended treatment option at this point.

11. **E.** Treatment of first-episode CDI should include oral vancomycin or fidaxomicin. Metronidazole should be avoided, if at all possible, for the treatment of CDI in all settings. IV vancomycin does not readily achieve appropriate concentrations in the GI tract and thus would be ineffective. While fidaxomicin is an appropriate choice, it is significantly more expensive than oral vancomycin for CDI treatment and thus oral vancomycin should be used initially in this patient.

12. **A.** CDI is problematic and can contaminate and spread readily if appropriate precautions are not taken. Hand sanitizer is not appropriate in the prevention of CDI, so hand washing with soap and water is recommended. Rooms must be fully cleaned with chlorine-based disinfectants. *C. difficile* spores can remain on surfaces for long periods of time so caution needs to be taken with any possible infectious patient. And finally, respiratory precautions are not necessary for *C. difficile* patients, only stringent contact precautions.

13. **E.** Traveler's diarrhea can be from a number of different pathogens, either enterotoxigenic or dysentery. However, *Vibrio* spp. is an uncommon cause of traveler's diarrhea.

14. **D.** Although there are recommendations for certain people to have antimicrobial therapy with them while traveling, it is not recommended for most people. Acid-suppression could increase the risk of infection acquisition. Food and personal hygiene are of utmost importance in preventing traveler's diarrhea.

15. **A.** Food poisonings can occur with a large variety of pathogens. However, no antimicrobial therapy is recommended in patients with acute food poisoning. If the duration of the symptoms last longer than 24 hours, a patient should be seen by a physician and potential options delineated. Fluid replacement is appropriate in these patients as well.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 136: Gastrointestinal Infections and Enterotoxigenic Poisonings

Andrew M. Roecker; Brittany N. Bates

KEY CONCEPTS

KEY CONCEPTS

①Infectious diarrhea is a disease that causes significant morbidity and mortality worldwide. Its etiology includes various bacteria, viruses, and protozoans, with viral causes being most predominant globally.

②Two types of infectious diarrhea include watery or enterotoxigenic diarrhea and dysentery or bloody diarrhea. Common pathogens responsible for watery diarrhea are viruses and enterotoxigenic *Escherichia coli*. Common pathogens responsible for dysentery diarrhea are *Shigella* spp., *Campylobacter jejuni*, nontyphoid *Salmonella*, and enterohemorrhagic *E. coli*.

③Fluid and electrolyte replacement is the cornerstone of therapy for diarrheal illnesses. Oral rehydration therapy is preferred in most cases of mild and moderate diarrhea.

④The use of antibacterial therapy for infectious diarrhea is not commonly indicated due to the mild and self-limited nature of the infection, or viral etiology. Antibiotic therapy is recommended in cases of severe diarrhea, moderate-to-severe cases of traveler’s diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea in high-risk patients.

⑤Loperamide and diphenoxylate/atropine may offer symptomatic relief in patients with moderate watery diarrhea; however, use of antimotility agents should be avoided in patients with watery and dysentery diarrhea.

⑥Diarrheal illness can be largely prevented by procedures to prevent contaminated food or water supplies and with appropriate personal hygiene.

⑦Oral vancomycin or fidaxomicin are recommended as the initial therapy for patients with *Clostridioides difficile* infection.

⑧Common traveler’s diarrheal pathogens include enterotoxigenic *E. coli*, *Shigella* spp., *Campylobacter* spp., *Salmonella* spp., and viruses.

⑨Patient education on prevention strategies and appropriate self-treatment of traveler’s diarrhea is preferred, and prophylaxis with antibacterials is not recommended.

⑩Pathogens commonly responsible for food poisoning include *Staphylococcus* spp., *Salmonella* spp., *Shigella* spp., and *Clostridioides* spp.pa

BEYOND THE BOOK

BEYOND THE BOOK

Perform a literature search to identify investigational drugs and therapies for *Clostridioides difficile* infection (CDI) not addressed in the book chapter. Create a document that describes the proposed mechanism of action for each agent.

INTRODUCTION

Gastrointestinal (GI) infections and enterotoxigenic poisonings encompass a wide variety of medical conditions characterized by inflammation of the GI tract. Inflammation-induced vomiting and diarrhea are responsible for much of the morbidity and mortality of these conditions. Diarrhea is defined as a decrease in consistency of bowel movements (ie, unformed stool) and an increase in frequency of stools to three or more per day.[1,2] Acute diarrheal disease is commonly associated with diarrhea lasting less than 7 days, prolonged diarrhea lasts 7 to 13 days, persistent diarrhea lasts 14 to 29 days, and chronic diarrhea lasts 30 days or longer.

This chapter focuses on infectious etiologies of acute GI infections and enterotoxigenic poisonings. A wide variety of viral, bacterial, and parasitic pathogens are responsible for these infections. Chapter e138, "Parasitic Diseases," discusses the common protozoans that cause gastroenteritis. This chapter will focus on pathogenesis and management of common viral and bacterial etiologies. Because the clinical consequences of dysenteric diarrhea can be more severe compared with cases of watery diarrhea, the chapter is organized accordingly. Epidemiology, clinical presentation, diagnosis, treatment, and prevention strategies are discussed for all GI infections generally, and further elaborated in subsequent sections for specific diseases such as *Clostridioides difficile* infection, traveler's diarrhea, and foodborne illnesses.

EPIDEMIOLOGY

Dehydration resulting from acute infectious diarrhea is the second leading cause of mortality in children younger than 5 years, killing 525,000 annually.[2] Globally, 1.7 billion cases of infectious diarrhea occur yearly and cause over 1.39 million deaths.[2,3] The incidence of diarrhea for all children younger than age 5 years is 2.9 episodes per child per year. The incidence of diarrhea is higher in younger children, with 4.5 episodes per child per year among children aged 6 to 11 months, compared with 2.3 episodes per child per year among children aged 24 to 59 months.[2,3] Younger children also have a higher risk of death from acute dehydrating diarrhea, and diarrheal disease is still the leading global cause of malnutrition in children younger than 5 years.[2] Although the incidence of childhood diarrhea has been declining, diarrhea remains a major health problem in children, especially in those younger than 1 year.

In the United States, 179 million episodes of acute gastroenteritis occur each year, resulting in nearly 500,000 hospitalizations and more than 5,000 deaths.[4–7] The highest mortality risk from infectious diarrhea in the United States occurs in the elderly, which contrasts to the developing world where the risk of death is highest among young children.[4] Twenty-five percent of all hospitalizations and 85% of all mortality associated with diarrhea involved the elderly (age 60 years and older).[4] In addition to children and the elderly, other groups at risk for GI infections include travelers and campers, patients in chronic care facilities, military personnel stationed abroad, and immunocompromised patients.

ETIOLOGY

① The etiology of GI infections and enterotoxigenic poisonings includes a wide variety of viruses, bacteria, and parasites, although the specific incidence of each is difficult to quantify. Etiologic agents are rarely identified due to the infrequent collection of stool samples, or inability of many laboratories to detect the full range of pathogenic organisms. In this chapter, discussions of pathogens responsible for enterotoxigenic diarrhea focus on viral pathogens (rotavirus and norovirus), enterotoxigenic *Escherichia coli* (ETEC), and cholera. Common pathogens associated with dysenteric diarrhea discussed will be *Shigella* spp., *Salmonella* spp., *Campylobacter* spp., enterohemorrhagic *E. coli* (EHEC), *Yersinia enterocolitica*, and *C. difficile*. Characteristics of watery and dysenteric diarrhea and common pathogens responsible for them are outlined in Table 136-1.

TABLE 136-1

Acute Infectious Diarrhea Clinical Syndromes: Watery Versus Dysentery

	Watery	**Dysentery**
Percentage of patients	90-95	5-10
Stools		
Appearance	Watery	Bloody
Volume	Increased: ++/+++	Increased: +/++
Number per day	<10	>10
Reducing substances	0 to +++	0
pH	5-7.5	6-7.5
Occult blood	Negative	Positive
Fecal polymorphonuclear cells	Absent or few	Many
Mechanisms	• Toxins • Reduced absorption	• Toxins • Mucosal invasion
Complications • Dehydration • Others	• Could be severe • Acidosis, shock, electrolyte imbalance	• Mild • Tenesmus, rectal prolapse, seizures
Etiology	*Vibrio cholerae*	*Shigella* spp.
	Enterotoxigenic *Escherichia coli* (ETEC)	*Salmonella* spp.
	Rotaviruses	*Campylobacter* spp.
	Noroviruses	*Yersinia* spp.
		Enterohemorrhagic *E. coli* (EHEC)
		Clostridioides difficile

Viruses are now the leading global cause of infectious diarrhea. Noroviruses, previously known as Norwalk-like viruses, account for greater than 90% of viral gastroenteritis among all age groups, and 50% of outbreaks worldwide. In the United States, noroviruses have been responsible for about 21% of all acute gastroenteritis cases in young children with outpatient visits, emergency department visits, and annual hospitalizations numbering 627,000, 281,000, and 14,000, respectively.[8] Outbreaks occur throughout the year and have been documented in families, healthcare systems, cruise ships, and college dormitories.

In infants and children, rotavirus, a double-stranded, wheel-shaped, RNA virus, is the most common cause of infectious diarrhea globally, and 1 million people die annually from the infection.[9] In the United States, approximately 3.5 million cases of diarrhea, 500,000 physician visits, 50,000 hospitalizations, and 20 deaths occur each year in children younger than 5 years. Rotavirus is a ubiquitous contagion, infecting the vast majority of children younger than 5 years. After the initial infection, 40% of children are protected against subsequent rotavirus infection, 75% are protected against subsequent gastroenteritis, and up to 88% are protected against severe gastroenteritis. After more extensive vaccination coverage for rotavirus in recent years, hospitalizations from this infection have significantly decreased.[9] Other viral etiologies include astrovirus, enteric adenovirus, pestivirus, coronavirus, and enterovirus. These viruses are increasingly identified as causative etiologies of diarrhea. Characteristics of viral pathogens causing gastroenteritis are outlined in Table 136-2.

TABLE 136-2

Characteristics of Agents Responsible for Acute Viral Gastroenteritis

Virus	Peak Age of Onset	Time of Year	Duration	Mode of Transmission	Common Symptoms
Rotavirus	6 months to 2 years	October to April	3-7 days	Fecal–oral, water, food	Nausea, vomiting, diarrhea, fever, abdominal pain, lactose intolerance
Norovirus	All age groups	Peak in winter	2-3 days	Fecal–oral, food, water, environment	Nausea, vomiting, diarrhea, abdominal cramps, myalgia
Astrovirus	<7 years	Winter	1-4 days	Fecal–oral, water, shellfish	Diarrhea, headache, malaise, nausea
Enteric adenovirus	<2 years	Year-round	7-9 days	Fecal–oral	Diarrhea, respiratory symptoms, vomiting, fever
Pestivirus	<2 years	NR	3 days	NR	Mild
Coronavirus-like particles	<2 years	Fall and early winter	7 days	NR	Respiratory disease
Enterovirus	NR	NR	NR	NR	Mild diarrhea, secondary organ damage

NR, not reported.

② Bacterial causes of acute gastroenteritis in the United States account for more than 5 million cases of diarrhea annually; however, these are vastly underreported and a causative pathogen is identified in less than 3% of cases.[4] FoodNet in 2019 identified 25,866 laboratory confirmed infections, resulting in 6,164 hospitalizations and 122 deaths from these infections.[4,10] Common pathogens responsible for watery diarrhea in the United States are norovirus and ETEC, while those most commonly associated with dysentery diarrhea are *Campylobacter* spp., EHEC, *Salmonella* spp., and *Shigella* spp. Other organisms that are responsible for dysentery include *Aeromonas* spp., noncholera *Vibrio*, and *Y. enterocolitica*. Characteristics of acute bacterial pathogens causing gastroenteritis are summarized in Table 136-3.

TABLE 136-3

Characteristics of Acute Bacterial Gastroenteritis

Bacteria	Incubation Period	Duration	Mode of Transmission	Common Symptoms
Watery Diarrhea				
Vibrio cholerae	2-3 days	1-3 days	Contaminated food or water with human feces usually in areas of inadequate treatment of sewage and drinking water	Profuse watery diarrhea, vomiting, and leg cramps Death can occur within hours without treatment
Enteroaggregative *E. coli*	NR	NR	Contaminated food or water with animal or human feces	Chronic, watery, mucoid, secretory diarrhea with low-grade fever in immunocompromised persons (HIV infections)
Enteroinvasive *E. coli*	10-18 hours	NR	Contaminated food or water with animal or human feces	Watery diarrhea in young children in the developing world
Enteropathogenic *E. coli*	9-12 hours	NR	Contaminated food or water with animal or human feces	Acute onset of profuse watery diarrhea, vomiting, and low-grade fever in young children (<2 years of age) in the developing world
Enterotoxigenic *E. coli*	1-3 days	3-4 days	Contaminated food or water with animal or human feces	Watery diarrhea and abdominal cramping
Dysentery Diarrhea				
Campylobacter jejuni	2-5 days	5-7 days	Contaminated food (particularly poultry), water, or contact with infected animals	Diarrhea (often bloody), cramping, abdominal pain, and fever
Enterohemorrhagic *E. coli*	3-4 days	5-7 days	Contaminated food (particularly cattle) or water with animal or human feces	Severe stomach cramps, diarrhea (often bloody), and vomiting
				Approximately 5%-10% develop hemolytic uremic syndrome
Nontyphoid *Salmonella*	12-36 hours	1-5 days	Contaminated food, water, or contact with infected animals	Diarrhea (sometimes bloody), fever, and abdominal cramps
Shigella	1-3 days	1-7 days	Fecal–oral Contaminated food or water with infected human feces	Watery or bloody diarrhea (8-10 stools/day), severe abdominal pain, fever, and malaise
Yersinia	4-7 days	1-3 weeks	Contaminated food or water	Fever, abdominal pain, and diarrhea (often bloody)

NR, not reported.

Cholera has been rare in the United States because of advanced water and sanitation systems, although slight increases in its incidence have occurred in recent years without clear causes. It is endemic on the Indian subcontinent and sub-Saharan Africa with five countries, Democratic Republic of the Congo, Haiti, Somalia, the United Republic of Tanzania, and Yemen, causing 80% of all cases.[11–13] *Vibrio cholerae* is a gram-negative bacillus sharing similar characteristics with the family Enterobacterales. Cholera is caused by toxigenic *V. cholerae* serogroups O1 or O139. Infections due to *V. cholerae* result in severe and voluminous diarrhea that can quickly result in dehydration. Approximately half of those persons infected with *V. cholerae* O1 are symptomatic, whereas only 1% to 5% of those infected with *V. cholerae* O139 manifest symptoms.[12,13] Vaccination is available to affected areas and to people traveling to those areas that might help in reducing prevalence and severity of disease.[13]

E. coli is a gram-negative bacillus commonly found in the human GI tract, and *E. coli*–associated diarrhea may be differentiated into several distinct categories based on pathogenic features of diarrheal disease: enteroaggregative *E. coli* (EAEC), EHEC, enteroinvasive *E. coli* (EIEC), enteropathogenic *E. coli* (EPEC), and ETEC. ETEC occurs most commonly, and accounts for about half of all cases of *E. coli* diarrhea. There are an estimated 79,000 cases of ETEC in the United States each year.[4] ETEC is also the most common cause of traveler's diarrhea and a common cause of food- and water-associated outbreaks. Infections with EIEC and EPEC are primarily a disease of children in developing countries.[14] EAEC strains are implicated in persistent diarrhea (≥14 days) in human immunodeficiency virus (HIV)-infected patients.[15] EHEC, also known as Shiga toxin–producing *E. coli* (STEC), causes watery diarrhea that becomes bloody in 1 to 5 days in 80% of patients.[14]

EHEC is believed to be the major etiologic factor responsible for the development of hemorrhagic colitis and hemolytic uremic syndrome (HUS). The annual disease burden of STEC in the United States is more than 20,000 infections and as many as 250 deaths; however, the failure of many clinical laboratories to screen for this organism greatly complicates any estimates.[16] In the United States, STEC causes 50% to 60% of all EHEC infections, but in the southern hemisphere, including Argentina, Australia, Chile, and South Africa, non-STEC serotypes are often more prevalent. Non-STEC strains generally produce a lower frequency of dysentery than STEC-positive strains (62% vs 85%).

The *Campylobacter* spp. are flagellated, curved, gram-negative rods. Although there are 14 different species, *Campylobacter jejuni* is the species responsible for more than 99% of *Campylobacter*-associated gastroenteritis. Approximately 2.4 million persons are affected each year in the United States, involving almost 1% of the entire population.[4]

Salmonella enterica is a gram-negative bacilli belonging to the family Enterobacterales. The most prevalent *S. enterica* serotypes are Typhi and Paratyphi, which cause enteric fever. Gastroenteritis is caused by *S. enterica* serotypes Typhimurium or Enteritidis. In the United States, the largest burden of *Salmonella* infection is due to nontyphoidal serotypes, causing approximately 1.4 million cases of salmonellosis, 16,000 hospitalizations, and 600 deaths, occurring annually.[17]

Approximately 165 million cases of shigellosis occur worldwide with 450,000 cases from the United States annually.[18,19] *Shigella* spp. are gram-negative bacilli belonging to the family Enterobacterales. Four species most often associated with disease are *Shigella dysenteriae* type 1, *Shigella flexneri*, *Shigella boydii*, and *Shigella sonnei*.[18,19] *Shigella sonnei* and *S. flexneri* are the most common causes of gastroenteritis in the United States. The other two *Shigella* spp. are more commonly acquired during travel to developing countries. Poor sanitation or personal hygiene, inadequate water supply, malnutrition, and increased population density are associated with an increased risk of *Shigella* gastroenteritis epidemics.

Yersinia spp. are non–lactose-fermenting gram-negative coccobacilli that are widely distributed in nature. The genus *Yersinia* includes six species known to cause disease in humans. *Yersinia enterocolitica* and, to a lesser extent, *Y. pseudotuberculosis* are most likely associated with intestinal infection, but overall both are a relatively infrequent cause of diarrhea and abdominal pain. More than 50 serotypes of *Y. enterocolitica* exist; of these, serotypes 0:3, 0:8, and 0:9 are associated most frequently with enterocolitis.[20] Children are most likely to experience illness with *Y. enterocolitica* infection.

PATHOPHYSIOLOGY

Acute gastroenteritis and its resulting diarrhea are caused by altered movement of ions and water resulting in increased colonic secretion. Under normal conditions, the GI tract has tremendous capacity to absorb fluid and electrolytes, allowing only 100 to 200 mL of fluid to be excreted in the stool daily.[21] The classic enteric pathogen that causes secretary diarrhea is *V. cholerae*, but ETEC and rotavirus also cause watery diarrhea and are much more predominant etiologies in the United States.

V. cholerae is an enteric pathogen that causes classical secretory diarrhea due to changes in ion secretion and absorption. Among the toxins produced by *V. cholerae*, the most important is cholera toxin.[11] Cholera toxin consists of two subunits, A and B. The B subunits are responsible for delivery of the A subunit into the cell. The A subunit stimulates adenylate cyclase, which increases intracellular cyclic adenosine monophosphate (cAMP) and results in protein kinase A–mediated activation of cystic fibrosis transmembrane conductance regulator. This leads to increased chloride secretion and decreased sodium absorption producing the severe watery diarrhea characteristic of the disease.[21] The toxin likely acts along the entire intestinal tract, but most fluid loss occurs in the duodenum. The net effect of the cholera toxin is isotonic fluid secretion early in the intestinal tract that exceeds the absorptive capacity of the latter intestinal tract.

ETEC also causes watery diarrhea characterized by severe intestinal water secretion by producing plasmid-mediated enterotoxins: heat-labile toxin and heat-stable toxin. The heat-labile toxin has two subunits (A and B) that have similar antigenic properties and action on the gut mucosa as cholera toxin. Heat-labile toxins increase chloride secretion via activation of cAMP. The net effect is luminal accumulation of electrolytes that draws water into the intestine, and production of a cholera-like secretory diarrhea.[22] Heat-stable toxin is thought to be nonantigenic and produces watery diarrhea by acting on the small intestine.

Rotavirus induces changes in transepithelial fluid balance, and causes malabsorption as a consequence of destruction of the epithelial lining of intestine, and vascular damage and ischemia in villi. Once rotavirus infects small intestinal villus cells, viroplasms are formed and its toxin, nonstructural protein 4, is released. The viral enterotoxin increases intracellular calcium, and the increase in calcium disrupts microvillus cytoskeleton, as well as barrier function. Changes to the villi include shortening of villus height, crypt hyperplasia, and mononuclear cell infiltration of the lamina propria.[23]

Inflammatory diarrhea is caused by two groups of organisms—enterotoxin-producing, noninvasive bacteria (eg, EAEC, EHEC) or invasive organisms (eg, *Campylobacter* spp., *Salmonella* spp., *Shigella* spp.). The enterotoxin-producing organisms adhere to the mucosa, activate cytokines, and stimulate the intestinal mucosa to release inflammatory mediators. Invasive organisms, which can also produce enterotoxin, invade the intestinal mucosa to induce an acute inflammatory reaction, involving the activation of local and systemic cytokines and inflammatory mediators.

Ingestion of as few as 10 to 200 viable organisms of the *Shigella* spp. causes disease in healthy adults.[18,19] *Shigella* multiply and spread within the submucosa of the small bowel, but they rarely extend beyond the mucosa. Inflammatory diarrhea is caused by the pathogens invading the epithelial barrier through M cells where they encounter and eliminate macrophages. The destruction of macrophages after emergence from M cells causes an initial release of interleukin (IL)-1β. This initial inflammatory process is exacerbated by free bacteria binding to toll-like receptor that causes the production of IL-6 and IL-8. Both IL-1β and IL-8 attract polymorphonucleocytes.[24] Release of polymorphonucleocytes activates chloride secretion and subsequent diarrhea. Degranulation and release of toxic substances by neutrophils cause ulceration of the epithelium, distortion of the crypts, death to intestinal epithelium, sloughing of mucosal cells, bloody mucoid exudate into the gut lumen, and submucosal accumulation of inflammatory cells with microabscess formation.[25] Microabscesses eventually may coalesce, forming larger abscesses. *Shigella* will frequently affect the entire colon. In addition to the virulence characteristics of invasiveness, *S. dysenteriae* type 1 and, to a lesser degree, *S. flexneri* and *S. sonnei* produce a cytotoxin or Shiga toxin, which can lead to HUS.[14]

The pathogenicity of EHEC is related to the production of Shiga-like toxins, so named because of their resemblance to the Shiga toxin of *S. dysenteriae*.[21] The cytotoxic effect of Shiga-like toxins disrupts the mucosal integrity of the large intestine, causing diarrhea. In addition, the toxin is able to pass through the intestinal epithelium to reach the endothelial cells lining small blood vessels that supply the gut, kidney, and other viscera, causing the myriad metabolic events that could eventually lead to HUS.

CLINICAL PRESENTATION

Gastroenteritis is an illness characterized by diarrhea, which may be accompanied by nausea, vomiting, fever, and abdominal pain. For effective diagnosis and management, it is important to distinguish noninflammatory diarrhea that produces watery diarrhea from inflammatory diarrhea or dysentery. Most enteric pathogens produce acute diarrhea and pathogens associated with dysentery will often result in grossly bloody stools and mucus. Systemic symptoms of gastroenteritis, such as fever, are often associated with dysentery of infectious origin. Symptoms of enteric pathogens that cause watery and dysentery diarrhea are listed in Table 136-1.

A physical examination and careful history that includes information about symptoms and symptom duration, the number of individuals affected, and recent history of travel, diet, and medications are important factors in making a diagnosis. Infections with norovirus or ETEC will often result in mild, self-limiting disease, whereas cholera will commonly produce severe dehydrating diarrhea. Infections with enteric pathogens such as *Campylobacter* spp., EHEC, *Salmonella* spp., *Shigella* spp., and *Y. enterocolitica* can result in severe symptomatology due to dysentery. The utilization of serum C-reactive protein (CRP) in young adult patients with infectious diarrhea may be able to help differentiate between noninflammatory and inflammatory causes.[26] Assessing CRP could assist with diagnosis, prognosis, and treatment selection. The clinical presentation of acute viral and bacterial gastroenteritis is summarized in Tables 136-2 and 136-3, respectively.

③ Stool culture is an important tool in making an organism-specific diagnosis and determining susceptibility to antimicrobial agents. Due to the low yield, stool cultures are not recommended in most mild-to-moderate watery diarrhea. Instead, indications for stool cultures include dysenteric diarrhea, persistent diarrhea in immunocompromised patients (ie, persons aged 65 years and older with comorbid diseases, neutropenia, or HIV infection), and diarrhea where an outbreak is suggested.[1] An appropriately obtained stool culture identifies the presence of *Campylobacter*, *Salmonella*, and *Shigella* spp. The yield of stool cultures for other pathogens is increased if the test is ordered specifically based on history and physical examination. For dysenteric diarrhea, the laboratory should be instructed to evaluate for EHEC including STEC (*E. coli* O157:H7). In hospitalized patients who develop diarrhea 3 days after hospitalization or in those with recent exposure to antimicrobials or chemotherapy, stool specimen should be sent for *C. difficile* toxins A and B. In addition to stool cultures, microscopic examination for fecal polymorphonuclear cells, or a simple immunoassay for the neutrophil marker lactoferrin, can further provide evidence of an inflammatory process and increase the yield of cultures in patients presenting with dysenteric diarrhea.[1]

Complications

Complications associated with acute diarrhea most likely result from dehydration so treatment focuses primarily on rehydration therapy, regardless of the etiology. Dysenteric diarrhea is more likely to have severe complications, especially in children younger than 5 years and in elderly. Bacteremia is the most common complication of gastroenteritis and can be seen after infections with nontyphoid *Salmonella*, *C. jejuni* or *C. fetus*, and *Y. enterocolitica*.[16] Nontyphoid *Salmonella* is most common in children younger than 5 years, elderly, and patients with hemoglobinopathy, malaria, or immunosuppression. Bacteremia due to *Campylobacter* spp. has been reported in patients with HIV infection, malignancy, transplantation, and hypogammaglobulinemia. *Y. enterocolitica* bacteremia has been rarely reported, but has an increased prevalence in patients with diabetes mellitus, severe anemia, hemochromatosis, iron overload (frequent transfusion), cirrhosis, malignancy, and in the elderly.[27] Persistent bacteremia with these pathogens will commonly result in prolonged intermittent fever with chills. Potentially complicating the diagnosis, stool cultures frequently are negative and leukocyte counts are often within the normal range. Vascular complications such as seeding of atherosclerotic plaques or aneurysms in arterial vessels occur in 10% to 25% of adults with bacteremia. Localized infections involving bone, cysts, heart, kidney, liver, lungs, pericardium, and spleen develop in 5% to 10% of patients with bacteremia.

A severe complication in patients infected with EHEC is HUS. HUS is defined by the triad of acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia and is more commonly observed in children younger than 5 years and in the elderly.[28] Approximately 2% to 7% of cases infected with STEC strains are complicated by development of HUS, which increases mortality associated with this infection. *S. dysenteriae* type 1 can also cause HUS, although more rarely than observed with EHEC.[18]

Shigella infection may also lead to complications such as generalized seizures, sepsis, toxic megacolon, perforated colon, arthritis, and protein-losing enteropathy. Mortality is rare, but it may be more likely with *S. dysenteriae* type I. Less than 3% of persons who are infected with *S. flexneri* will later develop Reiter syndrome, characterized by pains in the joints, irritation of the eyes, and painful urination. This can lead to chronic arthritis.[29]

Infection with *C. jejuni* has been associated with Guillain-Barré syndrome (GBS), but the relationship is not well understood.[30] The risk of developing GBS after *C. jejuni* infection appears to be low (approximately 1 case of GBS per 1,000 *C. jejuni* infections). The weakness associated with GBS usually starts in the legs, with difficulty in walking, and may progress to a complete paralysis of all extremities that lasts several weeks and usually requires intensive care.

Approximately 10% to 30% of adult patients develop a reactive arthritis 1 to 2 weeks after recovery from gastroenteritis secondary to *S. flexneri*, *Salmonella* spp., *C. jejuni*, and *Y. enterocolitica*. This arthritis, involving the knees, ankles, toes, fingers, and wrists, usually resolves in 1 to 4 months but may persist in approximately 10% of patients.[30] This complication is more common in persons with the HLA-B27 antigen.

A general complication that could occur long after an infectious gastroenteritis, especially with dysentery and toxin-mediated dysentery, is postinfectious irritable bowel syndrome (IBS). This is classified as IBS symptoms for at least 3 months following an episode of gastroenteritis or traveler's diarrhea showing recurrent abdominal pain or discomfort.[31] Albeit rare, some long-term complications associated with these infections strengthen the need for appropriate diagnosis and treatment.

TREATMENT

Mortality associated with infectious diarrhea has declined substantially in the past two decades, especially among children younger than 1 year. Preventative measures including improved sanitation, breast-feeding and weaning practices, and increased use of oral rehydration therapy (ORT) for affected individuals are responsible for the decrease in case-fatality rates.

General Approach to Treatment

The cornerstone of management for all GI infections and enterotoxigenic poisonings is to prevent dehydration by correcting fluid and electrolyte imbalances. In mild, self-limiting acute gastroenteritis, a diet of oral fluids and easily digestible foods is recommended. In patients with severe dehydrating watery diarrhea and dysenteric diarrhea, IV rehydration therapy, antibiotics, and/or antimotility treatments are needed.

Rehydration Therapy

Initial assessment of fluid loss is essential for successful rehydration therapy and should include acute weight loss, as it is the most reliable means of determining the extent of water loss. However, if accurate baseline weight is not available, clinical signs are helpful in determining approximate deficits (Table 136-4). Physical assessment generally is more reliable in young children and infants than in adults.

TABLE 136-4

Clinical Assessment of Degree of Dehydration in Children Based on Percentage of Body Weight Loss[a]

Variable	**Minimal or No Dehydration (<3% Loss of Body Weight)**	**Mild-to-Moderate (3%-9% Loss of Body Weight)**	**Severe (≥10% Loss of Body Weight)**
Blood pressure	Normal	Normal	Normal to reduced
Quality of pulses	Normal	Normal or slightly decreased	Weak, thready, or not palpable
Heart rate	Normal	Normal to increased	Increased (bradycardia in severe cases)
Breathing	Normal	Normal to fast	Deep
Mental status	Normal	Normal to listless	Apathetic, lethargic, or comatose
Eyes	Normal	Sunken orbits/decreased tears	Deeply sunken orbits/absent tears
Mouth and tongue	Moist	Dry	Parched
Thirst	Normal	Eager to drink	Drinks poorly; too lethargic to drink
Skin fold	Normal	Recoil in <2 seconds	Recoil in >2 seconds
Extremities	Warm, normal capillary refill	Cool, prolonged capillary refill	Cold, mottled, cyanotic, prolonged capillary refill
Urine output	Normal to decreased	Decreased	Minimal
Hydration therapy	None	ORS 50-100 mL/kg over 3-4 hours	• Lactated Ringer’s solution or normal saline 20 mL/kg over 15-30 minutes IV until mental status or perfusion improves • Followed by 5% dextrose/0.45% sodium chloride IV at higher maintenance rates or ORS 100 mL/kg over 4 hours
Replacement of ongoing losses	• For each diarrheal stool or emesis • <10 kg body weight: 60-120 mL ORS • >10 kg body weight: 120-240 mL ORS	Same as minimal dehydration	If unable to tolerate ORS, administer through nasogastric tube or administer 5% dextrose/0.45% sodium chloride with 20 mEq/L (mmol/L) potassium chloride IV

ORS, oral rehydration solution.

[a] Percentages vary among patients for each dehydration category; hemodynamic and perfusion status is most important; when unsure of category, therapy for more severe category is recommended.

③Fluid replacement is the cornerstone of therapy for dehydration due to diarrhea regardless of etiology. For the treatment of mild-to-moderate dehydration, ORT is superior to administration of IV fluids. Oral replacement therapy reverses dehydration in nearly all patients with mild-to-moderate diarrhea with 94% to 97% efficacy.[1] It offers advantages of being inexpensive, noninvasive, and not requiring inpatient administration. Moreover, thirst drives use of ORT and provides a safeguard against overhydration. Replacement of ongoing losses as well as continuation of normal feeding should also be addressed.

The necessary components of oral rehydration solutions (ORS) include carbohydrates (typically glucose), sodium, potassium, chloride, and water. Using both salt and glucose in the ORS takes advantage of glucose-coupled sodium transport in the small bowel and enhances sodium and subsequently water transport across intestinal walls. The World Health Organization/United Nations Children's Fund (WHO/UNICEF) endorsed a reduced osmolarity solution (osmolarity ≤250 mOsm/L) as the use of these solutions reduced stool volume, shortened duration of diarrhea, and decreased need for unscheduled IV therapy when compared with previously used ORS more than or equal to 310 mOsm/L.[32] The newer formulation of ORS less than or equal to 250 mOsm/L was, however, more likely to cause hyponatremia (blood sodium levels <130 mEq/L [mmol/L]).[33] If commercial ORS are unavailable, one can be roughly duplicated by mixing ½ teaspoon of salt with 6 teaspoons of sugar in 1 L of water.[34]

In restoring fluid and electrolyte balance in cholera infections, polymer-based ORS may be more efficacious than glucose-based ORS. Polymer-based ORS contains rice, wheat, sorghum, or maize. This polymer-based ORS releases glucose more slowly after digestion and, when absorbed in the small bowel, enhances the reabsorption of water and electrolyte secreted into the bowel lumen during diarrhea. Polymer-based ORS reduces the duration of diarrhea in adults with cholera when compared with glucose-based ORS more than or equal to 310 and less than or equal to 270 mOsm/L.[35]

Guidelines for rehydration therapy based on the degree of dehydration and replacement of ongoing losses are outlined in Table 136-4. ORS should be given in small and frequent volumes (5 mL every 2 to 3 minutes in a teaspoon or oral syringe). Nasogastric administration of ORS is an alternative method of administration in a child with persistent vomiting. For breast-fed infants, nursing should be continued. The composition of commercial ORS and commonly consumed beverages is listed in Table 136-5. Clear fluids, such as soft drinks, sweetened fruit drinks, chicken broth, and sports drinks, should be avoided in the treatment of dehydration. These hyperosmolar solutions may cause an osmotic diarrhea.

TABLE 136-5

Comparison of Common Solutions Used in Oral Rehydration and Maintenance

Product	Na (mEq/L)[b]	K (mEq/L)[b]	Base (mEq/L)	Carbohydrate (mmol/L)	Osmolarity (mOsm/L)
WHO/UNICEF (2002)	75	20	30	75	245
Pedialyte	45	20	30	140	250
Infalyte	50	25	30	70	200
Oralyte	60	20	0	90	260
Rehydralyte	75	20	30	140	250
Cola[a]	2	0	13	700	750
Apple juice[a]	5	32	0	690	730
Chicken broth[a]	250	8	0	0	500
Sports beverage[a]	20	3	3	255	330

[a] These solutions should be avoided in dehydration.

[b] Concentration of monovalent ions expressed in mEq/L is numerically equivalent to mmol/L concentration.

In the treatment of severe dehydration, the primary goal of therapy is rapid restoration of fluid losses, correction of metabolic acidosis, and replacement of potassium deficiency. Severely dehydrated patients should be resuscitated initially with IV lactated Ringer solution or normal saline to restore hemodynamic stability. Lactated Ringer solution is preferred initially over normal saline because normal saline does not assist in correcting a metabolic acidosis. As GI and renal perfusion should be addressed aggressively, rapid IV administration is preferred over prolonged administration regimens for restoring extracellular fluids and electrolytes.[36] After rehydration, maintenance fluid is given based on accurate recording of intake and output volumes. ORT should be instituted as soon as it can be tolerated.

Early refeeding with age-appropriate unrestricted diet is recommended in children. Early refeeding during or immediately following the start of rehydration did not increase the risk of complications such as unscheduled IV fluids, vomiting, or development of persistent diarrhea compared with late refeeding that ranged from 20 to 48 hours after start of rehydration.[36] Initially, easily digested foods such as bananas, applesauce, and cereal should be introduced and foods high in fiber, sodium, and sugar should be avoided. One caveat would be that lactase deficiency may be exacerbated among known lactase-deficient patients and may persist up to 10 days.

Antimicrobial Therapy

④ The indiscriminate use of antimicrobial therapy produces increases in antimicrobial resistance, side effects of antimicrobial agents, and the threat of superinfections owing to eradication of normal flora. Increasing fluoroquinolone resistance in *Campylobacter* and multidrug resistance in *Salmonella* spp. worldwide reinforces the importance of judicious use of antibiotics and prudent infection control measures.[37,38] Antibiotic therapy is recommended in severe cases of diarrhea, moderate-to-severe cases of traveler’s diarrhea, most cases of febrile dysenteric diarrhea, and culture-proven bacterial diarrhea. Antimicrobial therapy is not recommended in EHEC diarrhea as it may increase HUS risk.

Antibiotic therapy is recommended in severe cases of cholera and ETEC diarrhea. In cases of cholera, antibiotics shorten the duration of diarrhea, decrease fluid loss, and shorten the duration of the carrier state.[1,12] It is important to consider local susceptibility patterns in the selection of the antimicrobial regimen. In areas of high fluoroquinolone resistance, azithromycin has been effective in patients with cholera. In patients with ETEC diarrhea, empiric antibiotics reduce severity and duration of diarrhea. A short course of therapy with fluoroquinolones is the most commonly recommended therapy due to increased resistance among other drug classes.[39] Rifaximin has been effective for ETEC for travel in Mexico.[40] Further discussions of antibiotic prophylaxis and treatment can be found in the section on traveler's diarrhea. Table 136-6 summarizes antibiotic recommendations. Further details regarding treatment of *C. difficile*–associated diarrhea, traveler's diarrhea, and foodborne illnesses are discussed in respective sections.

TABLE 136-6

Recommendations for Antibiotic Therapy

Pathogen	Children	Adults
Watery Diarrhea		
Enterotoxigenic *Escherichia coli*	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Ciprofloxacin 750 mg orally once daily × 1-3 days. Alternatives: rifaximin 200 mg orally three times daily × 3 days; azithromycin 1,000 mg orally × 1 day *or* 500 mg orally daily × 3 days
Vibrio cholerae O1	Erythromycin 30 mg/kg/day divided every 8 hours orally × 3 days; azithromycin 10 mg/kg/day given orally once daily × 3 days	Doxycycline 300 mg orally × 1 day Alternatives: azithromycin 500 mg orally once daily × 3 days; ciprofloxacin 750 mg orally once daily × 3 days; ceftriaxone IV
Dysenteric Diarrhea		
Campylobacter species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3-5 days; erythromycin 30 mg/kg/day divided into two to four doses orally × 3-5 days	Azithromycin 500 mg orally once daily × 3 days Alternatives: ciprofloxacin 750 mg orally once daily × 7 days
Salmonella Nontyphoidal[a]	Ceftriaxone 100 mg/kg/day divided IV every 12 hours × 7-10 days; azithromycin 20 mg/kg/day orally once daily × 7 days	Ceftriaxone 2 g IV/IM once; ciprofloxacin 750 mg orally once daily × 7-10 days; Alternatives: ampicillin 250-500 mg orally every 6 hours × 7 days; azithromycin 500 mg orally once daily × 7 days; Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days For immunocompromised patients, duration should be increased to 14 days for both fluoroquinolones and azithromycin
Shigella species[a]	Azithromycin 10 mg/kg/day given orally once daily × 3 days; ceftriaxone 50 mg/kg/day given IV once daily × 3 days	Azithromycin 500 mg orally once daily x 3 days; ceftriaxone 2 g IV/IM once; ciprofloxacin 750 mg orally once daily × 3 days; Alternatives: ampicillin 250-500 mg orally every 6 hours × 7 days; Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days
Yersinia species[a]	Treat as children with shigellosis	Trimethoprim-sulfamethoxazole 160/800 mg twice daily × 7 days Alternatives: cefotaxime IV or ciprofloxacin 750 mg orally once daily × 7 days
Traveler's Diarrhea		
Prophylaxis[a]		None recommended
Treatment		Azithromycin 1,000 mg orally × 1 day or 500 mg orally daily × 3 days, Ciprofloxacin 750 mg orally × 1 day or 500 mg orally twice daily × 3 days; levofloxacin 500 mg orally daily × 3 days, ofloxacin 400 mg twice daily x 1-3 days, rifamycin SV 388 mg twice daily x 3 days, rifaximin 200 mg three times daily × 3 days

[a] For high-risk patients only. See the preceding text for the high-risk patients in each infection.

Antibiotic therapy is indicated in at-risk and febrile patients with dysenteric diarrhea. In shigellosis, antibiotics shorten the period of fecal shedding and attenuate the clinical illness. Antibiotic therapy is reserved for the elderly, those who are immunocompromised, children in daycare centers, malnourished children, and healthcare workers. In the United States, *Shigella* spp. remain susceptible to fluoroquinolones. Fluoroquinolone resistance among *Shigella* spp. is of increasing concern in developing countries, and azithromycin may be a better choice in patients with a recent history of travel to a developing region.[1,18] Similar antibiotic regimens can be used for high-risk patients who develop *Yersinia* bacteremia (ie, infants younger than 3 months and patients with cirrhosis or iron overload) or in patients with bone and joint infections.[41] With Campylobacteriosis, antibiotics are not useful unless started within 4 days of the start of the illness because they do not shorten the duration or severity of diarrhea and only shorten the duration of bacterial excretion. Antibiotics are warranted in patients with high fevers, severe bloody diarrhea, prolonged illnesses (more than 1 week), pregnancy, and immunocompromised states, including HIV infection. Fluoroquinolone resistance among *Campylobacter* spp. has increased, and is now 10% to 13% in the United States and 41% to 88% in Europe and Asia. Resistance may be the result of the use of fluoroquinolone antibiotics in poultry and other animal feed, and the frequent use of these agents internationally in treating enteric infections. Macrolides like azithromycin are recommended especially in patients with a recent history of travel to Asia.[39]

Nontyphoid *Salmonella* infection leads to bacteremia in approximately 8% of otherwise healthy adults. However, patients with increased risk of bacteremia should be treated with antibiotics if appropriate diagnosis is made. High-risk patients include neonates or infants younger than 1 year, persons older than 50 years, and patients with primary or secondary immunodeficiency such as acquired immunodeficiency syndrome (AIDS) or chemotherapy-induced inflammatory bowel disease, sickle cell disease, vascular abnormalities (prostatic heart valve or abdominal aneurysm), or prosthetic joints.[18] If cultures are positive for Salmonellosis and antibacterial therapy is warranted, susceptibility testing should be done for appropriate targeted therapy due to concern of resistance. *Salmonella enterica* serotype Typhi can cause enterocolitis and is a risk for typhoid fever. Although this pathogen is less prevalent, recent data have shown extensive drug resistance (susceptible to carbapenem or macrolide only), especially when travel to certain areas of the world (eg, Pakistan) were involved.[42] When treatment is required, it is important to take a full patient history to see if a patient may have a drug-resistant pathogen as the causative agent.

Outcomes of some bacterial diarrheal illnesses may be worsened by the use of antibacterials, therefore precluding their use. In patients infected with EHEC, use of a fluoroquinolone or trimethoprim-sulfamethoxazole may increase the risk of HUS by increasing the production of Shiga-like toxin.[1,41] Empiric antimicrobial therapy should be withheld when clinical suspicion is high due to the high local prevalence EHEC, patient clinical presentation suggestive of EHEC infection, or a known foodborne outbreak of dysentery with an incubation period of longer than 2 days. Antibiotics should not be given to infants or children due to a higher incidence of HUS in this population. Treatment of EHEC infection is primarily limited to supportive care, which may include fluid replacement therapy, hemodialysis, hemofiltration, transfusion red blood cells and/or platelets, and other interventions as indicated clinically. Severe disease may lead to chronic kidney failure and potential need of renal transplantation.

Antimotility Agents

⑤ Antimotility drugs such as diphenoxylate/atropine and loperamide offer symptomatic relief in patients with watery diarrhea by reducing the number of stools. However, in both enterotoxigenic and dysenteric diarrhea, slowing of fecal transit time with these agents is thought to result in extended toxin-associated damage, worsening symptomatology and leads to complications. Therefore, antimotility drugs should be avoided if possible and are not recommended in patients with toxin-mediated dysenteric diarrhea (ie, EHEC, pseudomembranous colitis, shigellosis). However, some evidence suggests that in adults with dysenteric diarrhea these agents do not appear to be harmful if given concomitantly with antibacterial therapy.[41]

Probiotics

Probiotics are preparations of microorganisms and most commercial products have been derived from food sources, particularly cultured milk products (ie, lactobacilli and bifidobacteria). When used in the treatment or prophylaxis of infectious diarrhea and antibiotic-associated diarrhea, efficacy is variable. Most individual studies have not shown significant benefit from the use of probiotics and meta-analyses have shown conflicting results, with one demonstrating efficacy when trials were assessed in aggregate[43] and another demonstrating no benefit.[44] Significantly decreased rates of CDI followed lactobacillus use in patients receiving 2 or more days of systemic antibacterials.[45] No serious adverse effects have been reported in otherwise healthy persons; however, there are data suggesting a rare but increased incidence of fungemia or bacterial sepsis with probiotic use. With confounding data both supporting and refuting the use of probiotics for prevention, the decision should be based upon patient-specific criteria.

Oral Zinc Supplementation

Zinc deficiency is largely due to inadequate dietary intake and is common in many developing countries where morbidity and mortality associated with acute diarrhea in children remains high. In children older than 6 months who demonstrate moderate signs of malnutrition, zinc supplementation may shorten the duration of diarrhea by approximately 27 hours (95% CI −14.62 to −39.34).[46] Therefore, oral zinc supplementation of 20 mg/day for 1 to 2 weeks may have an additional benefit over ORS alone in reducing childhood mortality in developing countries. Common side effects include metallic taste and vomiting. At high doses, zinc supplementation may cause epigastric pain, lethargy, and fatigue.

PREVENTION OF GASTROINTESTINAL INFECTIONS

⑥Public health measures of improved water supply and sanitation facilities and the quality control of commercial products are important for the control of the majority of GI infections. In addition, following simple rules of personal hygiene and safe food preparation can prevent many diarrheal diseases. Hand washing with soap and running water is instrumental in preventing the spread of illness and should be emphasized for caregivers and persons with diarrheal illnesses. Safe food handling and preparation practices can significantly decrease the incidence of certain enteric infections.

Reporting suspected outbreaks and cases of notifiable illness to local health authorities is vital to investigation of threats of enteric infection arising from increasingly global and industrialized food supplies. The reporting of specific infectious diseases to the appropriate public health authorities is the cornerstone of public health surveillance, outbreak detection, and prevention and control efforts.

Vaccines are used to boost specific immune processes directed against the bacteria themselves or against adherence appendages, cytotoxins, or enterotoxins. Unfortunately, there are only a few vaccines available for prevention of gastroenteritis. Vaccines for typhoid fever are the parenteral Vi capsular polysaccharide vaccine (ViCPS) and the oral live-attenuated Ty21a vaccine.[47] Efficacy rates for both vaccines range from 50% to 80%. The ViCPS is indicated for children who are 2 years of age or older, and a booster dose is administered 2 years after the first. The Ty21a vaccine is indicated for children 6 years or older; one capsule should be swallowed whole every other day for a total of four doses at least 1 week before the potential exposure. A booster should be taken every 5 years if continued protection is needed.

In the United States, routine rotavirus vaccination is recommended for all infants beginning at age 2 months. There are two vaccines, RotaTeq (RV5) and Rotarix (RV1), available for reducing rotaviral gastroenteritis.[48] The RV5 vaccine is a live, oral vaccine that offers 74% efficacy against gastroenteritis of any severity and 98% efficacy against severe disease. This vaccine also decreased office visits by 86%, emergency department visits by 94%, and hospitalizations by 96%. The RV1 vaccine is a live-attenuated human rotavirus vaccine. This vaccine has clinical efficacy of 79% against gastroenteritis of any severity and 96% efficacy against severe rotavirus disease. Rotarix reduced hospitalizations by 100% and medically attended visits by 92% in the first rotavirus season, and reduced hospitalizations by 96% through two seasons.[48] The RV5 vaccine is administered orally in a three-dose series at ages 2, 4, and 6 months while the RV1 vaccine is administered orally in a two-dose series at ages 2 and 4 months. The first dose may be given between 6 weeks and 14 weeks and 6 days of age and all doses should be given before 8 months of age. The vaccines are contraindicated in infants with severe allergic reactions to vaccine components, diagnosed with severe combined immunodeficiency, and with history of intussusception.[49]

Although not available in the United States, two oral vaccines against diarrheal pathogens are available in other countries. Dukoral consists of killed *V. cholerae* O1 organisms and the cholera B subunit, and is licensed in over 60 countries. Shanchol consists of killed whole cells from a mix of pathogenic strains of *V. cholerae* (O1 and O139) and is licensed in India.[11,13] Both vaccines are given in two doses (three doses of Dukoral are required for children aged 2-5 years) and administered about 7 to 14 days apart (up to 42 days apart for Dukoral). Dukoral must be administered with a buffer that requires 75 to 150 mL of clean water while Shanchol does not require the buffer. Both vaccines demonstrated protective efficacy of 47% to 87% after two doses but almost none after a single dose. Protection is achieved in approximately 1 week following the last dose and persists for approximately 2 years. The common side effects of the vaccines were considered mild and included abdominal pain, headache, fever, and nausea. The WHO does not require vaccination for international travel to or from endemic areas because vaccines require two doses and provide incomplete protection for a relatively short period of time.[13]

There are vaccines in development for common enteric pathogens including ETEC and *Shigella* spp. with the potential for combining them in a single vaccine. These are still in preliminary and animal-based studies, but could significantly affect global public health if they come to fruition for human administration, especially in the infants and children.[50]

EVALUATION OF THERAPEUTIC OUTCOMES

Appropriate follow-up care of patients with acute diarrhea is based on successful restoration of fluid losses. The clinical signs and symptoms that lead to the diagnosis also can assess adequate rehydration, and should be monitored frequently. With ORT preferred, routine laboratory testing often is unnecessary. Electrolytes should be measured in those receiving IV fluids, when oral replacement fails, or when signs of hypernatremia or hypokalemia are present. Follow-up stool samples to ensure complete evacuation of the infecting pathogen may be necessary only in patients who are at high risk to initiate or contribute to a community outbreak. All patients should be monitored for complications associated with the infecting pathogen, resolution of the diarrhea, and adverse reactions to the pharmacologic agents used. Prompt discharge of hospitalized patients is recommended when rehydration is achieved, IV fluids have not been required, oral intake equals or exceeds losses, or adequate education and medical follow-up are ensured. For most patients, discharge can occur in 16 to 24 hours.

CLOSTRIDIOIDES DIFFICILE

Epidemiology

C. difficile is the most commonly recognized cause of infectious diarrhea in healthcare settings with high rates of disease in the elderly and those exposed to antibiotic agents. While almost all antibiotics have been implicated in *C. difficile* infection (CDI), those most commonly associated include fluoroquinolones, clindamycin, carbapenems, and third-/fourth-generation cephalosporins. CDI often occurs during or shortly after completion of antimicrobial therapy; however, disease onset can be delayed for 3 or more months.[51] Other risk factors for acquisition of *C. difficile* include recent healthcare exposure, chemotherapy, patients undergoing gastrointestinal surgery or receiving tube feeding, and potentially those receiving acid suppressive medications. While some studies show an association between *CDI* and acid suppressing medications, such as proton pump inhibitors (PPIs) and histamine-2 blockers, there is variability in the literature and a need for prospective randomized trials to confirm this link.[51,52]

Incidence of CDI was steadily rising in the early 2000s, appearing to peak around 2010 at approximately 500,000 cases annually in the United States and Europe. Growing concern for CDI, especially in the healthcare facilities, led to the creation of the Centers for Disease Control and Prevention (CDC) Emerging Infection Program (EIP) CDI tracking program. This program has been conducting population-based surveillance of *C. difficile* in 10 US cities since 2011 in order to estimate the national burden of CDI. While the epidemiology of CDI has remained relatively steady, trends indicate a decline in healthcare associated infecitons.[51,53] One confounding factor in the estimation of CDI incidence is the introduction of more sensitive tests, such as nucleic acid amplification tests (NAATs), which may lead to overdiagnosis.[53] Recurrent CDI is a major problem, with escalating risk of infection and increased mortality with subsequent infections.[51,52]

Etiology and Pathophysiology

C. difficile is a gram-positive spore-forming obligate anaerobic bacterium that may colonize the large intestine of healthy individuals, as well as those experiencing a symptomatic CDI. *C. difficile* is transmitted most commonly by the fecal-oral route through ingestion of *C. difficile* spores. Pathogenic CDI occurs when there is disruption of the bowel flora and/or an inadequate immune response. Two major toxins (toxin A [TcdA] and toxin B [TcdB]) are released and lead to a loss of integrity of colonic epithelial cells.[54] This mediates an inflammatory cascade that causes tissue damage and results in diarrhea. Initially, raised white and yellowish plaques form in the colon and the surrounding mucosa may become inflamed. With progression of disease, pseudomembranous plaques become enlarged and scattered over the colorectal mucosa resulting in pseudomembranous colitis.[51] The production of binary toxin, mutations causing hyperproduction of toxins, antibiotic resistance, increased sporulation, and mutations that increase adherence to the intestinal epithelium may contribute to the virulence and disease severity in the host. Some strains, such BI/NAP1/027, express multiple mutations that make it hypervirulent and are a cause of significant clinical concern.[54]

CLINICAL PRESENTATION

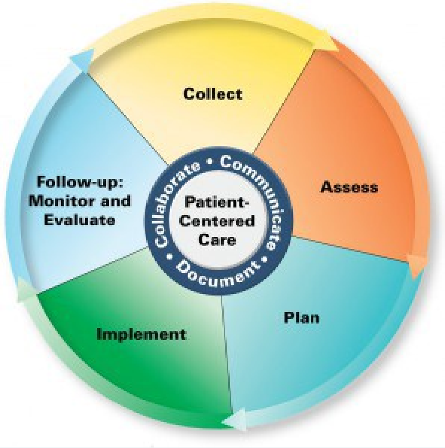
Symptoms of CDI range from mild diarrhea to fulminant disease and toxic megacolon. The diarrhea is typically watery and nonbloody, and is often associated with abdominal discomfort, fever, and leukocytosis. Patients with new and unexplained diarrhea (>3 unformed stools in 24 hours) should be evaluated for CDI.

Diagnosis of CDI is confirmed by identification of *C. difficile* organisms/toxin in stool or by colonoscopic or histopathologic findings revealing pseudomembranous colitis.[51]

The optimal test for laboratory diagnosis remains controversial. Nucleic acid amplification tests (NAAT), such as PCR-based toxin testing, are very popular in the United States and have high sensitivity and specificity; however, they should only be used in patients with acute diarrhea due to the possibility of detecting the toxins in asymptomatic patients.[51,52] Alternatively, a stepwise approach uses screening for glutamate dehydrogenase (GDH) as the initial step. GDH assays detect a common antigen present in all isolates of *C. difficile*, including nontoxigenic strains, thus requiring combination with another test (typically a toxin test with or without NAAT). The stepwise approach may be preferred in institutions where there is no criteria for stool submission in order to minimize the false positive results that may result with NAAT alone. Utility of toxigenic culture or cell culture neutralization assays are limited due to delayed results and high cost. Use of toxin enzyme immunoassay (EIA) alone has a low sensitivity and has largely been replaced by NAAT testing or incorporated into multistep algorithms along with GDH assays.[51,55]

PATIENT CARE PROCESS

Patient Care Process for *Clostridioides difficile* Infections (CDI)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (personal and family), including any previous episodes of CDI
- Social history (eg, tobacco/ethanol use) and dietary habits
- Current medications including OTC, herbal products, dietary supplements, acid suppressive medication, and previous antibiotic use (within the past 3 months)
- Characteristics of diarrhea including onset, number of episodes per day, and presence of blood
- Objective data
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
  - Labs including white blood cell count (WBC) and serum creatinine (SCr)
  - Stool sample to be tested for *C. difficile* toxins
  - Radiographic abdominal imaging if concern for ileus or megacolon

Assess

- Hemodynamic stability (eg, systolic BP <90 mm Hg, HR >110 bpm, O_2-sat <90% [0.90], RR)
- Radiographic studies for the presence of ileus, megacolon, or perforation
- Presence of CDI risk factors (age, antibiotic use, recent healthcare exposure, chemotherapy, GI surgery, tube feeding, acid suppressive medications)
- Ability to stop offending antibiotic agent if applicable
- Ability/willingness to pay for first-line treatment options
- Ability/willingness to try investigational therapies such as fecal microbiota transplant (if applicable for recurrent disease)
- Ability/willingness to pay for adjunctive therapy with bezlotoxumab

Plan*

- Drug therapy regimen including specific antibiotic dose, route, frequency, and duration (see Table 136-7)
- Discontinuation of offending antibiotic agent if applicable
- Monitoring parameters, such as resolution of diarrhea; frequency and timing of follow-up
- Patient education (eg, purpose of treatment, drug-specific information, and prevention of disease transmission)
- Self-monitoring for resolution of diarrhea and when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, infectious diseases, gasteroenterology)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up

Follow-Up: Monitor and Evaluate

- Resolution of diarrhea
- Presence of adverse effects (eg, CNS effects, metallic taste if metronidazole used; nausea, abdominal pain)
- Patient adherence to treatment plan using multiple sources of information
- Educate on limiting risk factors, such as antibiotic agents and acid suppressive medications

**Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 136-7

Clostridioides difficile Infection Severity and Treatment

Severity	Markers of Disease Severity	Recommended Treatment
Nonsevere	WBC ≤15,000 cells/mm^3 (15 × 10^9/L) SCr <1.5 mg/dL (133 µmol/L)	Vancomycin 125 mg orally four times daily for 10 days, OR Fidaxomicin[a] 200 mg orally twice daily for 10 days, OR Metronidazole[b] 500 mg orally every 8 hours for 10 days.
Severe	• WBC >15,000 cells/mm^3 (15 × 10^9/L) • SCr >1.5 mg/dL (133 µmol/L)	Vancomycin 125 mg orally four times daily for 10 days, OR Fidaxomicin 200 mg orally twice daily for 10 days
Fulminant	• Hypotension or shock • Ileus and/or megacolon	Metronidazole 500 mg IV every 8 hours *PLUS* vancomycin 500 mg every 6 hours via NG or orally (if ileus present use rectally)

[a] Fidaxomicin is preferred over vancomycin for patients with an initial CDI per IDSA/SHEA 2021 Focused Update.

[b] Metronidazole is an alternative therapy if other agents are unavailable or too costly.

Data from References 51,56.

NG, nasogastric; SCr, serum creatinine; WBC, white blood cell.

Treatment

Supportive care of CDI includes fluid and electrolyte replacement therapy, in addition to discontinuation of the offending antimicrobial if possible. Antimotility agents (such as diphenoxylate/atropine and loperamide) and exchange resins (such as cholestyramine and colestipol) have been used in CDI; however, in general their use is discouraged. Empiric therapy for CDI may be considered if the patient has a strong pre-test suspicion for CDI and is severely ill, or if there is an expected substantial delay in laboratory confirmation. Antibiotic therapy is based on disease severity and may vary for first episode or recurrent infection.[51] Table 136-7 outlines CDI disease severity and treatment regimens for initial episodes according to the IDSA/SHEA 2017 clinical practice guidelines. Differences exist among the available guidelines with regard to the definitions of nonsevere, severe, and fulminant or complicated CDI and slight treatment differences. There is a need for prospectively validated severity scores for patients with CDI.

⑦ In the United States, vancomycin and fidaxomicin are FDA approved for CDI. These treatments are well tolerated because they have minimal systemic absorption when administered orally; the main adverse effects are nausea and abdominal pain. The recommended treatment course is 10 days and repeat stool testing is not recommended as a test of cure.[51] For nearly three decades oral metronidazole was the drug of choice for mild-to-moderate CDI; however, it has fallen out of favor based on evidence showing it is significantly less effective than vancomycin or fidaxomicin. The IDSA/SHEA 2017 clinical practice guidelines recommended therapies for both nonsevere and severe CDI include oral vancomycin or fidaxomicin. However, based on emerging data demonstrating the sustained response and safety profile of fidaxomicin, it is now the preferred therapy for initial CDI episodes. Vancomycin represents an acceptable alternative if fidaxomicin is not available, which may be reasonable based on the cost and variable medical insurance coverage of fidaxomicin.[56] When used for CDI, vancomycin must be administered orally because IV vancomycin does not achieve adequate gut lumen concentrations for effective bacterial elimination. Vancomycin is available as a capsule and there are several reconstituted oral solution or suspensions commercially available. The IV formulation has also been compounded and administered orally as a cost-effective option.

In patients with severe/complicated or fulminant CDI the preferred regimen is combination therapy with IV metronidazole and vancomycin.[57] The route of vancomycin administration is patient-dependent; oral is preferred, but if ileus is present, rectal administration via retention enema is recommended at a dose of 500 mg in 100 mL of saline administered four times daily. Fidaxomicin has not been studied in complicated or fulminant disease, therefore is not recommended.[51] Some patients with fulminant disease may require surgical intervention with procedures such as diverting loop ileostomy or total colectomy.

Recurrent CDI (rCDI) is typically defined as an episode of CDI within 8 weeks from the previous episode. Approximately 15% to 35% of patients will have a recurrence and the rate nearly doubles after two or more recurrences.[58] Risk factors for recurrent CDI include increasing age, use of additional antimicrobials, gastric acid suppression, hypervirulent strains, and low antibody response to *C. difficile* toxins.[51,58] The preferred regimen for the first episode of rCDI is fidaxomicin standard dose or an extended-pulsed regimen (200 mg twice daily for 5 days, then once every other day for 20 days). Pulsed and tapered oral vancomycin is an alternative approach for the first recurrence. If metronidazole was used initially, then a standard vancomycin course can be utilized for the first recurrence. For patients with multiple recurrences fidaxomicin remains the preferred agent; however, pulsed/tapered vancomycin, vancomycin followed by rifaximin, or fecal microbiota transplantation (FMT) are acceptable alternatives.[56]

The importance of the gut microbiome and its relationship to primary and recurrent CDI has led to research on several emerging therapies for CDI. Multiple randomized controlled trials have shown efficacy of FMT with resolution rates up to 90%. The American College of Gastroenterology recommends FMT by colonoscopy or capsule formulation oral ingestion with rCDI.[58,59] Protocols that have been studied include stool suspension administered to the lower bowel (through colonoscopy, rectal tube, or enema) or the upper GI tract (through nasogastric or duodenal tube or gastroscope). Several microbiota products available in a capsule formulation are undergoing clinical trials and may be available for use in the near future.[6,60]

A monoclonal antibody, bezlotoxumab, that binds to and neutralizes toxin B is FDA approved as an adjunctive therapy to reduce the recurrence of CDI. The approved dose is 10 mg/kg IV as a single dose during antibacterial treatment for CDI. Bezlotoxumab is not an antibiotic and should not be used as monotherapy. For patients with rCDI within 6 months, IDSA/SHEA suggest bezlotoxumab use during the administration of standard of care antibiotics. There may be feasibility concerns, such as cost and logistics, with this approach. The benefit of adding bezlotoxumab to fidaxomicin is unknown at this time due to limited data with concurrent use of these agents.[56] While generally well tolerated, adverse effects were greater in patients with heart failure who were treated with bezlotoxumab; use in these patients should be considered carefully.[61]

Growing concern for CDI has led to an influx of new antibiotics targeting *C. difficile*. A common characteristic of many of the emerging therapies for CDI is a narrow spectrum of activity with the aim to minimize gut dysbiosis. As many of these agents complete phase III trials, it may change the treatment landscape for CDI in the future.[62]

Prevention of CDI involves both preventing the acquisition of the infection and stopping transmission of *C. difficile* spores to other patients. CDI has become the focus of antimicrobial stewardship efforts aimed at eliminating unnecessary antibiotics and reducing durations of therapy, which may be responsible for the plateau of CDI rates in recent years. The use of probiotics to prevent CDI remains controversial.[60,63]Some studies and meta-analyses have shown no benefit, while other evidence supports probiotic safety and efficacy in preventing CDI. Currently, there is insufficient evidence to recommend probiotics and they are not recommended by the American College of Gastroenterology.[1,51] Hand washing and contact precautions are imperative measures in preventing the spread of the organism. Alcohol is less effective at eliminating *C. difficile* spores compared to use of soap and water; however, there is no association between alcohol-based hand hygiene and increased CDI incidence. Nonetheless, the use of soap and water to prevent disease transmission is the preferred strategy. Proper environmental disinfecting measures in healthcare settings include use of sporicidal cleaning agents.[51,60,61,63]

TRAVELER'S DIARRHEA

Traveler's diarrhea describes the clinical syndrome manifested by malaise, anorexia, and abdominal cramps followed by the sudden onset of diarrhea that incapacitates many travelers. It interferes with planned activities or work in 30% of those affected. In particular, an increased risk lies with North Americans and Northern Europeans traveling to Latin America, southern Europe, Africa, and Asia. The highest risk is observed with patients with immunocompromised conditions, achlorhydria, inflammatory bowel disease, and people with chronic debilitating medical conditions. Overall, 30% to 70% of people traveling to high-risk areas will develop the illness.[39]

⑧The onset of symptoms usually occurs during the first week of travel but can occur anytime during the visit or after returning home. Traveler's diarrhea is caused by contaminated food or water. The most common pathogens are bacterial and include ETEC, *Campylobacter* spp., *Shigella* spp., and *Salmonella* spp.[10] Viral causes occur in less than 10% of cases with 80% to 90% of cases resulting from bacterial etiologies.[39] Enterotoxigenic *E. coli* is predominantly pathogenic in Latin America, Africa, and South Asia. The invasive enteric pathogens (*Campylobacter* spp., *Salmonella* spp., and *Shigella* spp.) are more important causes of traveler's diarrhea in Asia.

The severity of the syndrome is determined by the number of stools per day and the presence of cramping, nausea, and vomiting. Mild diarrhea is defined as one to three loose stools per day that are associated with abdominal cramps lasting less than 14 days. Moderate diarrhea indicates more than four loose stools daily associated with dehydration, and severe diarrhea is defined as the presence of blood in stools or a fever. Traveler's diarrhea is rarely life-threatening and in most cases, symptoms resolve in several days without treatment. Travelers to high-risk areas should pack a kit that includes a thermometer, loperamide, antibiotics (3-day course) (see "Treatment" section below), ORS salts, and a water purification method.[39]

Prevention

⑨Patient education in avoiding high-risk food and beverages should be the best method for minimizing the risk. High-risk foods and beverages include raw or undercooked meat and seafood, moist foods served at room temperature, fruits that cannot be peeled, vegetables, milk from a questionable source, hot sauces on the table, tap water, unsealed bottled water, iced drinks, and food from street vendors. Although education is readily available, the incidence of diarrhea was similar in travelers who followed advice and those who engaged in riskier eating habits.[64] Rationales for this include that cooking foods does not always kill pathogens and food should not be considered safe unless it is cooked until steaming hot. Nonetheless, advisement of avoidance measures regarding safe foods, beverages, and eating establishments is recommended to heighten awareness.

Bismuth subsalicylate 524 mg (two chewable tablets or 2 ounces) orally four times daily for up to 3 weeks is a commonly recommended prophylactic regimen.[39] Bismuth subsalicylate may inhibit enterotoxin activity and prevent diarrhea. Persons taking this regimen should be informed of adverse events, including temporary black discoloration of tongue and stools, and, rarely, tinnitus.

Although the efficacy of prophylactic antibiotics has been documented, their use is not recommended for most travelers due to the potential side effects of antibiotics (eg, photosensitivity), predisposition to other infections such as CDI or vaginal candidiasis, the increased risk of selection of drug-resistant organisms, cost, lack of data on the safety and efficacy of antibiotics given for more than 2 or 3 weeks, and availability of rapidly effective antibiotics for treatment. Prophylactic antibiotics are recommended only in high-risk individuals or in situations in which short-term illness could ruin the purpose of the trip, such as a military mission. A fluoroquinolone is the drug of choice when traveling to most areas of the world.[39] Due to fluoroquinolone resistance among *Campylobacter* spp., azithromycin can be considered when traveling to South and Southeast Asia.

Rifaximin is a nonabsorbed oral rifamycin that has activity against enteric pathogens and may have a role in the prevention of traveler's diarrhea in select populations. Rrifaximin 200 mg once, twice, or three times daily with meals for 2 weeks resulted in equal protection of 72% for each of the three dosing regimens compared with placebo.[40] Since rifaximin is effective against traveler's diarrhea due to noninvasive strains of *E. coli*, this agent should be reserved for travel regions where *E. coli* predominates, such as Latin America and Africa. Rifaximin has a tolerability and safety profile comparable to that of placebo. The concern with the class rifamycin is the emergence of resistance when used as monotherapy.

Treatment

The goals of treatment are to avoid dehydration, reduce the severity and duration of symptoms, and prevent interruption of planned activities. Fluid and electrolyte replacement should be initiated at the onset of diarrhea. ORT is generally not required in otherwise healthy individuals; flavored mineral water offers a good source of sodium and glucose. In infants and young children, elderly, and those with chronic debilitating medical conditions, ORT is recommended. For symptom relief, loperamide is preferred because of its quicker onset and longer duration of relief relative to bismuth. Standard dosing of loperamide is 4 mg orally initially and then 2 mg with each subsequent loose stool to a maximum of 16 mg/day in patients without bloody diarrhea and fever. Loperamide should be discontinued if symptoms persist for more than 48 hours. Other symptomatic therapy in mild diarrhea includes bismuth subsalicylate 524 mg every 30 minutes for up to eight doses.[39] As previously discussed, there is insufficient evidence to warrant the recommendation of probiotics.

Since behavioral modification has limited efficacy and chemoprophylaxis is not recommended in most travelers, the current recommendation relies on self-treatment. A single dose of antibiotic and up to 3 days of treatment will improve the condition within 24 to 36 hours, shortening the duration of diarrhea by 1 to 2 days.[39] A single dose of fluoroquinolone is recommended initially and if diarrhea is improved within 12 to 24 hours, antibiotics should be discontinued. Otherwise, it can be continued for up to 3 days. A fluoroquinolone is recommended when traveling to most areas of the world. Where fluoroquinolone-resistant *Campylobacter* is common, such as in South and Southeast Asia, azithromycin should be used.[39] Azithromycin can also be used in pregnant women and children younger than age 16 years. Empiric treatment of young children should be instituted with caution.

Rifaximin was as effective as a 3-day course of ciprofloxacin in shortening the duration of diarrhea in noninvasive traveler’s diarrhea. However, rifaximin was not as effective in patients with fever and bloody diarrhea and in those with invasive pathogens. Therefore, a 3-day course of rifaximin has been approved for the treatment of traveler’s diarrhea caused by noninvasive strains of *E. coli* in people 12 years or older and can be considered when traveling to areas where *E. coli*–associated traveler’s diarrhea is common, such as Mexico and Jamaica.[39]

For rapid improvement in symptoms, antibiotic therapy with adjunctive treatment with loperamide has shown benefit.[65] All clinical trials concluded that the combination therapy was safe, and the worsening of the disease with the use of antimotility treatment has not been encountered.

FOOD POISONING

⑩ Foodborne illnesses result from the ingestion of food containing pathogenic microorganisms that cause GI infections or preformed toxins that were produced by microorganisms that cause enterotoxigenic poisonings. In the United States, foodborne diseases cause approximately 76 million illnesses, 325,000 hospitalizations, and 5,200 deaths each year.[4] Foodborne transmission may account for up to 80% of acute gastroenteritis. However, the incidence and outbreaks of foodborne illness have declined in recent years.[66] Common enteric pathogens responsible for foodborne diseases have been discussed in the previous sections (*Campylobacter* spp., *E. coli*, norovirus, nontyphoidal *Salmonella*, *Shigella*). Common foodborne pathogens that cause enterotoxigenic poisonings include *Bacillus cereus*, *Clostridioides botulinum, Clostridioides perfringens*, and *Staphylococcus aureus*. Characteristics of pathogens responsible for foodborne illnesses are summarized in Table 136-8.

TABLE 136-8

Food Poisonings

Organism	Principal Foods	Peak Incidence (United States)	Time to Symptoms	Duration	Common Symptoms
Enterotoxigenic Poisonings					
Bacillus cereus	Fried rice, dairy products, spices, bean sprouts, vegetables	None	1-6 hours 6-24 hours	1 day 1 day	Nausea, vomiting Diarrhea
Clostridioides botulinum	Home-canned fruits, vegetables, meats, honey	None	18-36 hours		Double vision, blurred vision, drooping eyelids, slurred speech, difficulty swallowing, dry mouth, and muscle weakness
Clostridioides perfringens (type A)	Meats, poultry, gravies, dried or precooked foods	Fall, winter, spring	8-12 hours	1 day	Abdominal cramps, diarrhea
Staphylococcus aureus	Salad, pastries, ham, sandwiches, puddings, unpasteurized milk, cheese products	Summer	1-6 hours	1 day	Nausea, vomiting, abdominal cramps, diarrhea
GI Infections					
Campylobacter spp.	Poultry, dairy products, clams, water	Spring, summer	2-5 days	7 days	Diarrhea (may be bloody), cramping, abdominal pain, fever
Enteropathogenic *E. coli*	Water	None	1-3 days	5-7 days	Severe diarrhea, vomiting, dehydration
Enterotoxigenic *E. coli*	Water, ice, food	None	1-3 days	3-4 days	Profuse watery diarrhea, abdominal cramping
Salmonella spp.	Beef, poultry, water, eggs, dairy products	Summer	12-72 hours	4-7 days	Diarrhea (sometimes bloody), fever, abdominal cramps
Shigella spp.	Salad, water	Summer	1-2 days	5-7 days	Diarrhea (often bloody), fever, abdominal cramps
Vibrio cholerae	Water	None	2 hours to 5 days	2-3 days	Profuse watery diarrhea, vomiting, leg cramps
Vibrio parahemolyticus	Shellfish (oysters)	Spring, summer, fall	24 hours	3 days	Watery diarrhea, abdominal cramping, nausea, vomiting, fever, chills
Yersinia enterocolitica	Dairy products, raw or undercooked pork products	None	4-7 days	1-3 weeks	Fever, abdominal pain, diarrhea (often bloody)

Because foodborne disease can appear as sporadic cases or outbreaks, the diagnosis should be suspected whenever two or more people present with acute GI or neurologic manifestations after sharing a meal within the previous 72 hours. Important clues about etiologic agents can be gathered from demographic information (age, gender, etc.), the clinical syndrome, incubation period, and medical history, type of foods consumed, seasonality, and geographic location of the outbreak.

Enterotoxigenic poisonings result from ingestion of food contaminated by preformed toxins. Therefore, symptoms are rapid in onset, but most cases of food poisoning are of short duration with recovery occurring within 1 to 2 days. *B. cereus* causes two different types of clinical syndromes. The first one is characterized by a short incubation period and vomiting. The second syndrome has a longer incubation period and is characterized by diarrhea. Foodborne *C. perfringens* infection may present as two distinct syndromes. Type A organisms are seen in Western Hemisphere nations and result in a 24-hour illness characterized by watery diarrhea and epigastric pain. Type C organisms can be found in undercooked pork and occur in underdeveloped tropical regions. They can produce a toxin-related syndrome called *enteritis necroticans*, which is a coagulative transmural necrosis of the intestinal wall.[67] This syndrome can result in intestinal perforation leading to sepsis and mortality in approximately 40% of victims.

Foodborne botulism results from the ingestion of food contaminated with preformed toxins or toxin-producing spores from *C. botulinum*. Poisoning from *C. botulinum* is rare; only 110 cases are reported per year in the United States. Botulism is almost always associated with improper preparation or storage of food. Seven distinct toxins (A to G) have been described. The toxins prevent the release of acetylcholine at the peripheral cholinergic nerve terminal. Toxin activity has prompted the use of minute locally injected doses to treat select spastic disorders, such as blepharospasm, hemifacial spasm, and certain dystonias. Foodborne botulism is suspected when patients present with acute GI symptoms concurrently or just prior to the onset of a symmetric descending paralysis without sensory or central nervous system involvement. Diagnosis is made by culturing *C. botulinum* from the stool. The clinical presentation may resemble GBS associated with *C. jejuni* infection. The difference lies in the onset of neurologic symptoms, which typically occur 1 to 3 weeks after the onset of *C. jejuni* infection, and the condition usually is manifested by an ascending paralysis in *C. jejuni*–associated GBS.

Treatment consists primarily of respiratory support and use of botulinum antitoxin. If evaluation is performed within several hours of ingestion, gastric lavage or induction of vomiting is suggested. Cathartics and enemas also can be used to remove residual toxin from the bowel, but they are contraindicated in cases of ileus. Botulinum antitoxin is a concentrated preparation of equine globulins obtained from horses immunized with toxins A, B, and E. Because trivalent antitoxin is equine in origin, patients should be tested for hypersensitivity before receiving the product intravenously. Newer and more effective methods of treatment and prevention are under development, including a botulinum toxin vaccine consisting of nontoxic botulinum fragments. Prevention always should be stressed. Botulinum toxins are heat labile and readily destroyed by 10 minutes of boiling. All home-canned foods should be processed according to directions and boiled, not just warmed, prior to consumption.

In foodborne illnesses, the cornerstone of therapy remains supportive care. ORT is preferred in replenishing and maintaining fluid and electrolyte balance, and IV fluid therapy should be reserved for those who are severely ill and cannot tolerate oral therapy. Antiemetics and antimotility agents offer symptomatic relief, but the latter should not be given in patients who present with high fever, bloody diarrhea, or fecal leukocytes. Antimicrobial therapy is not effective in the management of *S. aureus*, *C. perfringens*, or *B. cereus* food poisonings. In developed countries, many of the foodborne illnesses can be prevented with proper food selection, preparation, and storage. However, in developing countries, sanitation and clean water supply are larger concerns.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
cAMP	cyclic adenosine monophosphate

SELF-ASSESSMENT QUESTIONS

1. The most common cause of infectious diarrhea in American children is which of the following pathogens?

   A. *Vibrio cholerae*

   B. *Campylobacter jejuni*

C. *Yersinia enterocolitica*

D. *Escherichia coli*

E. Rotavirus

2. Which of the following pathogens is most commonly associated with dysentery (bloody) diarrhea?

   A. *Vibrio cholerae*

   B. *Escherichia coli*

   C. *Clostridioides difficile*

   D. *Yersinia enterocolitica*

3. Which of the following statements regarding the treatment of *E. coli*–related infectious diarrhea is FALSE?

   A. Initial treatment should include appropriate hydration with low-osmolar or isotonic fluid replacement.

   B. The use of antimotility agents, like loperamide, could potentially increase diarrheal symptoms due to prolonged exposure to bacterial toxin.

   C. Using fluoroquinolone agents for treatment of this infection is appropriate when bloody stools are present and serotype is undetermined.

   D. None of the above are FALSE.

4. Which of the following causes of dysentery diarrhea currently has an available vaccine in the United States that may prevent some species of the disease?

   A. Shigellosis

   B. Campylobacteriosis

   C. Salmonellosis

   D. Yersiniosis

   E. None of the above have available vaccine

5. Which of the following statements regarding rehydration therapy in a patient with gastroenteritis is FALSE?

   A. Intravenous fluid replacement is indicated in all pediatric patients with infectious diarrhea.

   B. Glucose and other simple sugars in high concentrations can worsen diarrhea in a patient acutely ill with gastroenteritis.

   C. If a patient presents with gastroenteritis and an ileus, intravenous fluid replacement is indicated.

   D. None of the above are FALSE.

6. Which of the following statements regarding diagnosis of *Clostridium difficile* infection (CDI) is/are TRUE?

   A. Diagnosis of CDI requires presence of bacterial-released toxin and a host response to that toxin.

   B. Testing for toxin production in CDI with solid, formed stools is appropriate to ensure eradication of the organism.

   C. CDI diagnosis requires anaerobic cultures for confirmation.

   D. All of the above are true.

7. According to current guidelines, what class of antimicrobials would be indicated for treatment in a 62-year-old patient with confirmed enterocolitis due to a *Salmonella* species?

   A. Cephalosporin

   B. Aminoglycoside

   C. Macrolide

   D. Carbapenem

8. Treatment for an adult with campylobacteriosis that started having bloody diarrhea 2 days ago should be initiated on which of the following medication?

   A. Ciprofloxacin

   B. Doxycycline

   C. Metronidazole

   D. Azithromycin

   E. No antimicrobial therapy is warranted

9. Which of the following viral causes of infectious gastroenteritis could be seen during the winter months and would be common in adults?

   A. Rotavirus

   B. Norovirus

   C. Astrovirus

   D. Coronavirus

10. A patient is diagnosed with CDI and has a WBC of 17,500 cells/mm^3 (17.5 x 10^9/L). Which of the following regimens would be an appropriate selection for treatment, according to the most recent guidelines for the treatment of CDI?

    A. Metronidazole 500 mg orally every 8 hours

    B. Vancomycin 125 mg orally every 6 hours

    C. Fidaxomicin 200 mg orally twice daily

    D. All of the above are appropriate

    E. Only TWO of the above are appropriate

11. According to current guidelines, a patient diagnosed with first-episode CDI that is determined to be critically ill (has systemic symptoms including hypotension) should be treated with which of the following for *C. difficile* treatment?

    A. Metronidazole orally

    B. Vancomycin orally

    C. Vancomycin intravenously

    D. Fidaxomicin orally

   E. Metronidazole intravenously + vancomycin orally

12. Which of the following statements is/are TRUE regarding CDI prevention?

   A. Hand washing with soap and water can help prevent person-to-person transmission of CDI.

   B. Room disinfection after a CDI patient is discharged must be performed with alcohol-based cleaners.

   C. *C. difficile* spores survive only hours outside the host, so time is another method of preventing CDI transmission.

   D. Respiratory precautions (masks and face shields) should be utilized when entering and taking care of a CDI patient.

   E. None of the above are true.

13. Which of the following would NOT be considered a common pathogen in causing traveler's diarrhea?

   A. Enterotoxigenic *Escherichia coli*

   B. Rotavirus

   C. *Shigella dysenteriae*

   D. *Vibrio cholerae*

   E. All of the above are common pathogens in traveler's diarrhea

14. Recommended prophylaxis for traveler's diarrhea should include which of the following?

   A. Education on proper food and personal hygiene

   B. Famotidine 20 mg orally twice daily while traveling

   C. Ciprofloxacin 750 mg orally once daily while traveling

   D. All of the above should be recommended

15. A patient is having some diarrhea and is diagnosed with food poisoning following eating potato salad and tapioca pudding at his family reunion. In all likelihood, the causative pathogen is *Staphylococcus aureus*. Which of the following antibacterials should be recommended for his treatment in combination with ORT?

   A. Ciprofloxacin

   B. Azithromycin

   C. Trimethoprim-sulfamethoxazole

   D. Linezolid

   E. No antibiotic therapy is warranted

SELF-ASSESSMENT QUESTION-ANSWERS

1. **E.** Diarrhea is a common malady in children, although more problematic in the developing world. In the United States, the most common pathogen is still viral pathogens so rotavirus is the most likely cause.

2. **D.** Dysentery diarrhea needs to be distinguished from enterotoxigenic (watery) diarrhea based on symptoms and pathogens. Although some pathogens may produce similar symptoms after prolonged illness, *Yersinia* spp. causes dysentery type diarrhea more commonly whereas the other

options are most commonly causes of enterotoxigenic diarrhea.

3. **C.** If only the pathogen is known and the serotype is not, we could precipitate hemolytic uremic syndrome if the serotype is E. coli O157:H7. Preference would be to avoid antimicrobials, if possible, or obtain serotype testing prior to initiating antimicrobial therapy with fluoroquinolones or any potential agent.

4. **C.** The only bacterial pathogen causing gastrointestinal infections that would have an available vaccine is *Salmonella* spp.

5. **C.** Fluid replacement therapy should be instituted for all patients with infectious diarrhea. However, intravenous therapy is not required in pediatric or adult patients unless certain severity criteria are met. The other statements are true.

6. **A.** Diagnosis of *C. difficile* infections require symptoms and a positive toxin test. Cultures are not recommended and solid stools should never be tested for *C. difficile*.

7. **A.** Treatment strategies for salmonellosis include ceftriaxone, ciprofloxacin, or ofloxacin. Of these options, ceftriaxone is a cephalosporin and the fluoroquinolones are not listed as an option. Recall there could be utility of other agents based on resistance profiles, but generally using ceftriaxone should be sufficient.

8. **A.** Because the patient is showing signs of dysentery diarrhea, antimicrobial therapy is often recommended for campylobacteriosis. Here the preferred agent is a macrolide and azithromycin would be the preferred option.

9. **D.** Although common causes of gastroenteritis in the pediatric population, viral causes are less common in adults. Of the choices, norovirus would be predominant in the adult population during winter months, if not bacterial. The other viruses are uncommon in adults.

10. **B.** Treatment for CDI is based upon symptoms and with this patient showing severe etiology, based upon the treatment guidelines, metronidazole should be avoided here and in general for treatment of *C. difficile*. Oral vancomycin or fidaxomicin is the recommended treatment option at this point.

11. **E.** Treatment of first-episode CDI should include oral vancomycin or fidaxomicin. Metronidazole should be avoided, if at all possible, for the treatment of CDI in all settings. IV vancomycin does not readily achieve appropriate concentrations in the GI tract and thus would be ineffective. While fidaxomicin is an appropriate choice, it is significantly more expensive than oral vancomycin for CDI treatment and thus oral vancomycin should be used initially in this patient.

12. **A.** CDI is problematic and can contaminate and spread readily if appropriate precautions are not taken. Hand sanitizer is not appropriate in the prevention of CDI, so hand washing with soap and water is recommended. Rooms must be fully cleaned with chlorine-based disinfectants. *C. difficile* spores can remain on surfaces for long periods of time so caution needs to be taken with any possible infectious patient. And finally, respiratory precautions are not necessary for *C. difficile* patients, only stringent contact precautions.

13. **E.** Traveler's diarrhea can be from a number of different pathogens, either enterotoxigenic or dysentery. However, *Vibrio* spp. is an uncommon cause of traveler's diarrhea.

14. **D.** Although there are recommendations for certain people to have antimicrobial therapy with them while traveling, it is not recommended for most people. Acid-suppression could increase the risk of infection acquisition. Food and personal hygiene are of utmost importance in preventing traveler's diarrhea.

15. **A.** Food poisonings can occur with a large variety of pathogens. However, no antimicrobial therapy is recommended in patients with acute food poisoning. If the duration of the symptoms last longer than 24 hours, a patient should be seen by a physician and potential options delineated. Fluid replacement is appropriate in these patients as well.

Chapter 137: Intra-Abdominal Infections

Alan E. Gross; Jamie L. Wagner; Keith M. Olsen

KEY CONCEPTS

KEY CONCEPTS

① Most intra-abdominal infections are caused by a defect in the gastrointestinal (GI) tract and are best treated by surgical drainage, resection, and/or repair.

② Primary peritonitis is generally caused by a single organism (*Staphylococcus aureus* in patients undergoing chronic ambulatory peritoneal dialysis [CAPD] or *Escherichia coli* in patients with cirrhosis).

③ Secondary peritonitis is usually caused by a mixture of bacteria, including enteric gram-negative bacilli and anaerobes, which enhance the pathogenic potential of the bacteria.

④ For peritonitis, early and effective IV fluid resuscitation and electrolyte replacement therapy are essential. A common cause of early death is tissue hypoperfusion precipitated by inadequate intravascular volume.

⑤ Treatment is generally initiated on a “presumptive” or empirical basis and should be based on the likely pathogen(s), local resistance patterns, and severity of illness.

⑥ Antimicrobial regimens for secondary peritonitis, determined by the severity of illness and microbiology data, include: (a) third-generation cephalosporin (ceftriaxone) with metronidazole, (b) piperacillin/tazobactam, (c) a carbapenem (imipenem, meropenem, or ertapenem), or (d) a quinolone (levofloxacin or ciprofloxacin) plus metronidazole or moxifloxacin alone.

⑦ Treatment of patients with peritoneal dialysis-associated peritonitis should include an antistaphylococcal antimicrobial, such as a first-generation cephalosporin (cefazolin) or vancomycin, as well as an agent with significant gram-negative bacterial activity such as a third-generation cephalosporin or aminoglycoside; intraperitoneal administration is preferred.

⑧ The duration of antimicrobial treatment should be 4 days after achievement of source control for most secondary peritonitis infections.

⑨ Patients treated for intra-abdominal infections should be assessed for the occurrence of drug-related adverse effects, particularly hypersensitivity reactions (β-lactam antimicrobials), diarrhea (most agents), fungal infections (most agents), and nephrotoxicity (aminoglycosides).

BEYOND THE BOOK

BEYOND THE BOOK

Activity 1:

Answer the questions for the case below on the basis of the information contained within the chapter and develop a treatment plan following the patient care process.

Case: A 59-year-old woman with history of cirrhosis secondary to alcohol abuse is admitted from an outside hospital for altered mental status and concern for hepatic encephalopathy. The patient lives at home, and the day before admission, the patient told her spouse that her stomach was hurting. The spouse expresses concern that the patient was not receiving lactulose for the past 1.5 weeks and missed her recent liver clinic appointment. The patient was initially admitted for less than 24 hours to an outside hospital and received unknown antibiotics before transfer to the current hospital. On exam, the patient is drowsy and not very responsive to questions. Patient appears jaundiced and is complaining of abdominal pain. No nausea, vomiting, or shortness of breath is observed.

Home medications:

Folic acid 1 mg orally every day

Lactulose 10 g orally twice a day

Magnesium oxide 400 mg orally twice a day

Pantoprazole 40 mg orally every day

Potassium chloride 20 mEq orally twice a day

Hydrochlorothiazide 25 mg orally every day

Spironolactone 25 mg orally every day

ALL: NKDA

Pertinent Labs:

Total bilirubin 11.5 mg/dL (197 µmol/L)

Direct bilirubin 3.9 mg/dL (67 µmol/L)

Alkaline phosphatase 68 U/L (1.13 µkat/L)

AST/ALT 65/27 U/L (1.08/0.45 µkat/L)

Albumin 2.3 g/dL (23 g/L)

Creatinine 0.7 mg/dL (62 µmol/L)

WBC 14.8 × 10^9/L (14,800/µL)

Hemoglobin 8.9 g/dL (89 g/L; 5.52 mmol/L)

Platelets 92 × 10^9/L (92,000/µL)

INR 3.2

No significant culture history

Vitals: Pulse 106 BPM, Respiratory rate 24 BPM, BP 145/65 mm Hg, O_2 Saturation 96% (0.96) on room air, Tmax 38°C

Diagnostic paracentesis on admission: Ascites fluid cell count/differential; Color: Yellow, cloudy; WBC: 8,080 cells/µL (8.08 × 10^9/L); RBC: 5,280 cells/µL (5.28 × 10^9/L); Neutrophil: 74% (0.74); Gram stain: negative

1. How do you classify this patient's infection?
    - A. Cholecystitis
    - B. Cholangitis
    - C. Spontaneous bacterial peritonitis
    - D. Secondary bacterial peritonitis
2. What laboratory data and patient symptoms support the diagnosis above?
3. What are the likely pathogens that could cause this syndrome?
4. What empiric therapy do you initiate?
    - A. Cefepime
    - B. Cefepime + metronidazole
    - C. Ceftriaxone
    - D. Ceftriaxone + metronidazole
    - E. Meropenem

Answers to Postclass Beyond the Book Activity 1 exercise:

1. C.

2. The patient has liver cirrhosis, which is a risk factor for spontaneous bacterial peritonitis (SBP). They present with fever, abdominal pain, and an ascitic fluid with >250/μL (0.25 × 10^9/L) PMN, which is suggestive of SBP. Although the Gram stain of the ascitic fluid was negative, the Gram stain is often negative with low inoculum infections and/or in patients who have received antibiotic therapy.

3. SBP is typically monomicrobial. The most common pathogens are *Streptococcus* species and Enterobacterales such as *Escherichia coli* and *Klebsiella* spp. Notably, anaerobes are not a common cause of SBP.

4. C. Ceftriaxone is the correct response, given it provides adequate empiric activity for the pathogens listed in question 3. Furthermore, it does not provide unnecessary broad coverage for anaerobes (responses B, D, and E are incorrect) or *Pseudomonas* (responses A, B, and E are incorrect).

Activity 2: Watch the video entitled "Diverticulosis and Diverticulitis Assessment" by Picmonic (https://www.picmonic.com/pathways/nursing/courses/standard/medical-surgical-nursing-pathophysiology-296/inflammatory-intestinal-disorders-1421/diverticulosis-and-diverticulitis-assessment_1147). This 1.5-minute video provides a general overview of diverticulosis and diverticulitis. The video is useful to enhance student understanding regarding the COLLECT and ASSESS steps in the patient care process.

INTRODUCTION

Intra-abdominal infections are those contained within the peritoneal cavity or retroperitoneal space. The peritoneal cavity extends from the undersurface of the diaphragm to the floor of the pelvis and contains the stomach, small bowel, large bowel, liver, gallbladder, and spleen. The duodenum, pancreas, kidneys, adrenal glands, great vessels (aorta and vena cava), and most mesenteric vascular structures reside in the retroperitoneum. Intra-abdominal infections may be generalized or localized, complicated or uncomplicated, and community- or healthcare-associated. Uncomplicated intra-abdominal infections are confined within visceral structures, such as the liver, gallbladder, spleen, pancreas, kidney, or female reproductive organs, and do not extend into the peritoneum, while complicated intra-abdominal infections involve anatomical disruption, extend beyond a single organ, and yield peritonitis and/or abscess.

Community-acquired intra-abdominal infections are usually caused by the patient's own microflora, are present within 48 hours of admission to the hospital, and occur in patients that do not have significant history of healthcare exposure (ie, presence of an invasive device; known methicillin-resistant *Staphylococcus aureus* [MRSA] infection or colonization; or healthcare facility residence, dialysis, or surgery in the prior 12 months). Healthcare-associated intra-abdominal infections can be classified as either community-onset or hospital-onset. Community-onset infection occurs in patients presenting from the community with the aforementioned healthcare exposure risk factors, while hospital-onset infection is defined by infection occurring after 48 hours of hospitalization.[1]

Peritonitis is defined as the acute inflammatory response of the peritoneal lining to microorganisms, chemicals, or foreign-body injury. This chapter deals only with peritonitis of infectious origin. An *abscess* is a purulent collection of fluid separated from surrounding tissue by a wall consisting of inflammatory cells and adjacent organs. It usually contains necrotic debris, bacteria, and inflammatory cells. These processes differ considerably in presentation and approach to treatment.

EPIDEMIOLOGY

Peritonitis may be classified as primary, secondary, or tertiary. Primary peritonitis, also called *spontaneous bacterial peritonitis*, is an infection of the peritoneal cavity without an evident source in the abdomen. Bacteria may be transported from the bloodstream to the peritoneal cavity, where the inflammatory process begins. In secondary peritonitis, a focal disease process is evident within the abdomen. Secondary peritonitis may involve perforation of the gastrointestinal (GI) tract (possibly because of ulceration, ischemia, or obstruction), postoperative peritonitis, or posttraumatic peritonitis (blunt or penetrating trauma). Tertiary peritonitis occurs in critically ill patients, and it persists or recurs at least 48 hours after attempted management of primary or secondary peritonitis.[2,3]

① Primary peritonitis occurs in both children and adults, although the incidence and mortality rates in both populations have been declining.[4] Primary peritonitis develops in up to 10% to 30% of patients with alcoholic cirrhosis.[4-7] Patients undergoing chronic ambulatory peritoneal dialysis (CAPD) average one episode of peritonitis every 20 to 33 months.[8,9] Secondary peritonitis may be caused by perforation of a peptic ulcer; traumatic perforation of the stomach, small or large bowel, uterus, or urinary bladder; appendicitis; pancreatitis; diverticulitis; bowel infarction; inflammatory bowel disease; cholecystitis; operative contamination of the peritoneum; or diseases of the female genital tract, such as septic abortion, postoperative uterine infection, endometritis, and salpingitis. Diverticulitis is the eighth most frequent diagnosis for outpatients in the United States and is responsible for over 216,000 hospital admissions in 2012.[10] Appendicitis is also a common cause of intra-abdominal infections. More than 300,000 appendectomies are performed in the United States for suspected appendicitis each year.[11] Most healthcare-associated intra-abdominal infections occur as complications following intra-abdominal surgeries.

ETIOLOGY

Primary peritonitis in adults occurs most commonly in association with alcoholic cirrhosis, especially in its end stage, or with ascites caused by postnecrotic cirrhosis, chronic active hepatitis, acute viral hepatitis, congestive heart failure, malignancy, systemic lupus erythematosus, or nephritic syndrome. It may also result from the use of a peritoneal catheter for dialysis or CNS ventriculoperitoneal shunting for hydrocephalus. Rarely, primary peritonitis occurs without apparent underlying disease.

Potential causes of bacterial peritonitis include inflammatory processes of the GI tract or abdominal organs, bowel obstruction, vascular occlusions that may lead to gangrene of the intestines, and neoplasia that may cause intestinal perforation or obstruction (Table 137-1). Other possible causes include those resulting from traumatic injuries, postoperative infections, or solid organ transplant in the abdomen.

Diverticulitis arises from inflammation of diverticula, intestinal protrusions into the surrounding muscle layer, and can be considered as both uncomplicated and complicated intra-abdominal infections. Risk factors for diverticulitis include smoking, physical inactivity, obesity, diets low in fiber and high in processed carbohydrates and red meat, and use of nonsteroidal anti-inflammatory drugs (NSAIDs).[10]

TABLE 137-1

Causes of Bacterial Peritonitis

Primary (spontaneous) bacterial peritonitis
    Cirrhosis with ascites
    Nephrotic syndrome
    Peritoneal dialysis (may be secondary to catheter site infection)
Secondary bacterial peritonitis
Miscellaneous causes
    Diverticulitis
    Appendicitis
    Inflammatory bowel diseases
    Salpingitis
    Biliary tract infections
    Necrotizing pancreatitis
    Neoplasms
    Intestinal obstruction
    Perforation
Mechanical GI problems
    Any cause of small bowel obstruction (adhesions, hernia)
Vascular causes
    Mesenteric arterial or venous occlusion (atrial fibrillation)
    Mesenteric ischemia without occlusion
Trauma
    Blunt abdominal trauma with rupture of intestine
    Penetrating abdominal trauma
Iatrogenic intestinal perforation (endoscopy)
Intraoperative events
    Solid organ transplant in the abdomen
Peritoneal contamination during abdominal operation
Leakage from GI anastomosis

GI, gastrointestinal.

Abscesses are the result of chronic inflammation and may occur without preceding generalized peritonitis. They may be located within one of the spaces of the peritoneal cavity or within one of the visceral organs and may range from a few milliliters to a liter or more in volume. These collections often have a fibrinous capsule and may take from a few weeks to years to form.

The causes of intra-abdominal abscess overlap those of peritonitis and, in fact, may occur sequentially or simultaneously. Appendicitis is the most frequent cause of abscesses. Other potential causes of intra-abdominal abscess include pancreatitis, diverticulitis, lesions of the biliary tract, genitourinary tract infections, perforation in the abdomen, trauma, and leaking intestinal anastomoses. In addition, pelvic inflammatory disease in women may lead to formation of a tubo-ovarian abscess. For some diseases, such as appendicitis and diverticulitis, abscesses occur more frequently than generalized peritonitis. Protein–calorie malnutrition, antecedent steroid therapy, and diabetes mellitus may also contribute to the formation of an intra-abdominal abscess.

Microflora of the Gastrointestinal Tract and Female Genital Tract

A full appreciation of intra-abdominal infections requires an understanding of the normal microflora within the GI tract. There are striking differences in bacterial species and concentrations of flora within the various segments of the GI tract (Table 137-2), and this bacterial environment usually determines the severity of infectious processes in the abdomen. Generally, the low gastric pH eradicates bacteria that enter the stomach. With achlorhydria, bacterial counts may rise to 10^5 to 10^7 organisms/mL (10^8 to 10^{10}/L). The normally low bacterial count may also increase by 1,000- or 10,000-fold with gastric outlet obstruction, hemorrhage, gastric cancer, and in patients receiving histamine 2 (H2)-receptor antagonists, proton pump inhibitors, or antacids.[12,13] A two- to threefold increase in spontaneous bacterial peritonitis has been demonstrated with the use of proton pump inhibitors.[12]

TABLE 137-2

Usual Microflora of the GI Tract

Site	Commonly Found Bacteria	Approximate Concentration (No. of Organisms/mL [×10^3/L])	
		Aerobes	Anaerobes
Stomach[a]	*Streptococcus, Lactobacillus*	10-100	Rare
Biliary tract	Normally sterile (*Escherichia coli, Klebsiella*, or enterococci in some patients)	0	0
Proximal small bowel	*Streptococcus* (including enterococci), *E. coli, Klebsiella, Lactobacillus*, diphtheroids	100	Few
Distal ileum	*E. coli, Klebsiella, Enterobacter*, enterococci, *Bacteroides fragilis, Clostridium*, peptostreptococci	10^4-10^6	10^5-10^7
Colon	*Bacteroides* spp., peptostreptococci, *Clostridium, E. coli, Klebsiella*, enterococci, *Enterobacter, Candida*, and many others	10^5-10^8	10^9-10^{11}

GI, gastrointestinal.

[a] With achlorhydria, acid suppressive therapy, gastric cancer, or gastric outlet obstruction, bacterial counts may rise to 10^5/mL (10^8/L).

The biliary tract (gallbladder and bile ducts) is sterile in most healthy individuals, but in people older than 70 years, those with acute cholecystitis, jaundice, or common bile duct stones, it is likely to be colonized by aerobic gram-negative bacilli (particularly *E. coli* and *Klebsiella* spp.) and enterococci.[14,15] Patients with biliary tract bacterial colonization are at greater risk of intra-abdominal infection.

In the distal ileum, bacterial counts of aerobes and anaerobes are quite high. In the colon, there may be 500 to 600 different types of bacteria in stool, with concentrations often reaching 10^{11} organisms/mL (10^{14}/L), and anaerobic bacteria outnumbering aerobic bacteria by more than 1,000 to 1.[16,17] Fortunately, most colonic bacteria are not pathogens because they cannot survive in environments outside the colon. Perforation of the colon results in the release of large numbers of anaerobic and aerobic bacteria into the peritoneum.

The colonic flora generally remains the same unless exposed to a broad spectrum of antimicrobials or a GI infectious process. In either case, the flora may change due to the antibiotic or infectious process and is often replaced by more pathogenic bacteria. Depending on the type of antibiotic and spectrum, the duration of use, route of administration, and distribution to the GI tract, antibiotics can cause shifts in the normal GI microflora leading to increased drug resistance.[18]

The lower female genital tract is generally colonized by a large number of aerobic and anaerobic bacteria. Anaerobes may number 10^9 organisms/mL (10^{12}/L) and often include lactobacilli, eubacteria, clostridia, anaerobic streptococci, and, less frequently, *Bacteroides fragilis.* Aerobic bacteria most often are streptococci and *Staphylococcus epidermidis*, and these may number 10^8 organisms/mL (10^{11}/L).

PATHOPHYSIOLOGY

Intra-abdominal infection results from bacterial entry into the peritoneal or retroperitoneal spaces or from bacterial collections within intra-abdominal organs. In primary peritonitis, bacteria may enter the abdomen via the bloodstream or the lymphatic system by transmigration through the bowel wall, through an indwelling peritoneal dialysis catheter, or via the fallopian tubes in females. Hematogenous bacterial spread (through the bloodstream) occurs more frequently with tuberculosis peritonitis or peritonitis associated with cirrhotic ascites. When peritonitis results from peritoneal dialysis, skin surface flora is introduced via the peritoneal catheter. In secondary peritonitis, bacteria most often enter the peritoneum or retroperitoneum as a result of perforation of the GI or female genital tracts caused by diseases or traumatic injuries. In addition, peritonitis or abscesses may result from contamination of the peritoneum during a surgical procedure or from an anastomotic leak. In diverticulitis, it is postulated that stool particles accumulate within the diverticula to either erode into the abdominal cavity or form an abscess.[10]

The physiologic characteristics of the peritoneal cavity determine the nature of the response to infection or inflammation within it. The peritoneum is lined by a highly permeable serous membrane with a surface area approximately that of skin. The peritoneal cavity is lubricated with less than 100 mL of sterile, clear yellow fluid, normally with fewer than 250 WBC cells/μL (0.25×10^9/L), a specific gravity below 1.016, and protein content below 3 g/dL (30 g/L).[4,19] These conditions change drastically with peritoneal infection or inflammation, as described below.

After bacteria are introduced into the peritoneal cavity, there is an immediate response to contain the invasion. Humoral and cellular defenses respond first, then the omentum adheres to the affected area. A limited bacterial inoculum is handled rapidly by defense mechanisms, including complement activation and a leukocyte response. Under certain conditions, bacteria are not contained and disseminate throughout the peritoneal cavity, resulting in peritonitis. This is more likely to occur in the presence of a foreign body, hematoma, dead tissue, a large bacterial inoculum, continuing bacterial contamination, and contamination involving a mixture of synergistic organisms.

When bacteria become dispersed throughout the peritoneum, the inflammatory process involves most of the peritoneal lining. There is an outpouring into the peritoneum of fluid containing leukocytes, fibrin, and other proteins that form exudates on the inflamed peritoneal surfaces and begin to form adhesions between peritoneal structures. This process, combined with a paralysis of the intestines (ileus), may result in confinement of the contamination to one or more locations within the peritoneum. Fluid also begins to collect in the bowel lumen and wall, and distension may result.

The fluid and protein shift into the abdomen (called *third-spacing*) may be so dramatic that circulating blood volume is decreased, which may cause a decrease in cardiac output leading to hypovolemic shock. Accompanying fever, vomiting, or diarrhea may worsen the fluid imbalance. A reflex sympathetic response, manifested by perspiration, tachycardia, and vasoconstriction, may be evident. With an inflamed peritoneum, bacteria and endotoxins are absorbed easily into the bloodstream (translocation), and this may result in septic shock.[4,5,19] Other foreign substances present in the peritoneal cavity potentiate peritonitis. These adjuvants, notably feces, dead tissues, barium, mucus, bile, and blood, have detrimental effects on host defense mechanisms, particularly on bacterial phagocytosis.

Many of the manifestations of intra-abdominal infections, particularly peritonitis, result from cytokine activity. Inflammatory cytokines, such as tumor necrosis factor-α (TNF-α), interleukin (IL) 1, IL-6, IL-8, and interferon-γ (INF-γ), are produced by macrophages and neutrophils in response to bacteria and bacterial products or in response to tissue injury resulting from the surgical incision.[4,19] These cytokines produce wide-ranging effects on the vascular endothelium of organs, particularly the liver, lungs, kidneys, and heart. With uncontrolled activation of these mediators, sepsis may result (see Chapter 142, “Sepsis and Septic Shock”).[20-22]

Peritonitis may result in death because of the effects on major organ systems. Fluid shifts, cytokines, and microorganism toxins may result in hypovolemia, hypoperfusion, and shock. Hypoalbuminemia may result from protein loss into the peritoneum, exacerbating intravascular volume loss. Pulmonary function may be compromised by the inflamed peritoneum, producing splinting (muscle rigidity caused by pain) that inhibits adequate diaphragmatic movement leading to atelectasis and pneumonia. Increased lung vascular permeability and resulting shunting of blood may induce onset of acute respiratory distress syndrome and associated hypoxemia and hypercarbia. With fluid loss and hypotension, renal and hepatic perfusion may be compromised, and acute renal and hepatic failures are potential threats.

If peritoneal contamination is localized but bacterial elimination is incomplete, an abscess results. This collection of necrotic tissue, bacteria, and WBCs may be at single or multiple sites and may be within one of the spaces of the peritoneal cavity or in one of the visceral organs. The location of the abscess is often related to the site of primary disease. For example, abscesses resulting from appendicitis tend to appear in the right lower quadrant or the pelvis; those resulting from diverticulitis tend to appear in the left lower quadrant or pelvis.

An abscess begins by the combined action of inflammatory cells (such as neutrophils), bacteria, fibrin, and other inflammatory mediators. Bacteria may release heparinases that cause local thrombosis and tissue necrosis or fibrinolysins, collagenases, or other enzymes that allow extension of the process into surrounding tissues. Neutrophils gathered in the abscess cavity die in 3 to 5 days, releasing lysosomal enzymes that liquefy the core of the abscess. A mature abscess may have a fibrinous capsule that isolates bacteria and the liquid core from antimicrobials and immunologic defenses.

Within the abscess, the oxygen tension is low, and anaerobic bacteria thrive; thus, the size of the abscess may increase because it is hypertonic, resulting in an additional influx of fluid. Hypertonicity promotes the formation of L-form bacteria, which are resistant to antimicrobial agents that disrupt cell walls. Abscess formation may continue and mature for long periods of time and may not be readily evident to either patient or physician. In some instances, the abscess may resolve spontaneously, and, infrequently, it may erode into adjacent organs or rupture and cause diffuse peritonitis. If the abscess erodes through the skin, it may result in an enterocutaneous fistula, connecting the peritoneum to skin, or in a draining sinus tract.

The overall outcome of an intra-abdominal infection depends on key factors: patient-specific risk factors, inoculum size, virulence of the contaminating organisms, the presence of adjuvants within the peritoneal cavity that facilitate infection, the adequacy of host defenses, source control, and the adequacy of initial treatment.[23-25]

Microbiology of Intra-Abdominal Infection

② The prevalence of pathogens has not appreciably changed in community-onset intra-abdominal infection, although susceptibility to antibiotics has decreased over time. Primary bacterial peritonitis is often caused by a single organism. In children, the pathogen is usually group A *Streptococcus*, *E. coli*, *Streptococcus pneumoniae*, or *Bacteroides* species.[26-29] When peritonitis occurs in association with cirrhotic ascites, *E. coli* is isolated most frequently. Other potential pathogens are: *Haemophilus influenzae*, *Klebsiella* spp., *Pseudomonas* spp., anaerobes, and *S. pneumoniae*.[30] Occasionally, primary peritonitis may be caused by *Mycobacterium tuberculosis.* Peritonitis in patients undergoing peritoneal dialysis is caused most often by common skin organisms, such as coagulase-negative staphylococci, *S. aureus*, streptococci, and enterococci. Gram-negative bacteria associated with peritoneal dialysis infections include *E. coli*, *Klebsiella* spp., and *Pseudomonas* spp.[9] The mortality rate from primary peritonitis caused by gram-negative bacteria is much greater than that from gram-positive bacteria.[4,5]

③ Because of the diverse bacteria present in the GI tract, secondary intra-abdominal infections are often polymicrobial.[16] The mean number of different bacterial species isolated from infected intra-abdominal sites ranged from 2.9 to 3.7, including an average of 1.3 to 1.6 aerobes and 1.7 to 2.1 anaerobes.[30,31] With proper anaerobic specimen collection, anaerobic organisms are isolated in most patients. In one report of patients with gangrenous and perforated appendicitis, an average of 10.2 different organisms was isolated from each patient, including 2.7 aerobes and 7.5 anaerobes.[32] Purely aerobic or anaerobic infections are uncommon, as are infections caused by fungi. Table 137-3 gives the frequencies with which specific bacteria were isolated from patients with peritonitis and other intra-abdominal infections.[33,34] Nosocomial infections tend to have a more diverse array of pathogens, are more likely to involve *Pseudomonas* spp., and have a higher likelihood of multidrug-resistance compared with isolates from community-acquired infections.[35]

TABLE 137-3

Pathogens Isolated from Patients with Intra-Abdominal Infection

	Secondary Peritonitis[33,35] (%)	Community-Acquired Infection[35] (%)	Nosocomial Infection[35] (%)
Gram-Negative Bacteria			
Escherichia coli	32-61	29	22.5
Enterobacter	8-26	5.2	8.0
Klebsiella	6-26	2.8	4.5
Proteus	4-23	1.7	2.4
Pseudomonas	5-13	5	13
Gram-Positive Bacteria			
Enterococcus	18-24	10.6	18
Streptococcus	6-55	13.7	10
Staphylococcus	6-16	3.1	4.8
Anaerobic Bacteria			
Bacteroides	25-80	13.7	10.3
Clostridium	5-18	3.5	3.4
Fungi	2-5	3	4

Visceral organ abscesses differ in character from the typical intra-abdominal abscess. Hepatic abscesses may be polymicrobial (involving *E. coli*, *Klebsiella* spp., and anaerobes) or occasionally may be caused by amoeba.[17] Pancreatic abscesses are often polymicrobial, involving enteric bacteria that ascend through the biliary system. Splenic abscesses usually result from hematogenous dissemination of bacteria, such as *E. coli, S. aureus*, *Proteus mirabilis*, *Enterococcus* spp., and *Klebsiella pneumoniae*, as well as anaerobes.[17] Pelvic inflammatory disease is associated initially with *Neisseria gonorrhoeae* or *Chlamydia trachomatis.* However, tubo-ovarian abscesses are usually polymicrobial, having a mix of gram-positive and gram-negative aerobes and anaerobes.

Bacterial Synergism

The size of the bacterial inoculum and the number and types of bacterial species present in intra-abdominal infections influence patient outcome. The combination of aerobic and anaerobic organisms appears to greatly increase the severity of infection. In animal studies, combinations of aerobic and anaerobic bacteria were much more lethal than infections caused by aerobes or anaerobes alone.

Facultative bacteria may provide an environment conducive to the growth of anaerobic bacteria.[16] Although many bacteria isolated in mixed infections are nonpathogenic by themselves, their presence may be essential for the pathogenicity of the bacterial mixture.[23] The role of facultative bacteria in mixed infections can include (a) promotion of an appropriate environment for anaerobic bacterial growth through oxygen consumption, (b) production of nutrients necessary for anaerobes, and (c) production of extracellular enzymes that promote tissue invasion by anaerobes.

Rat models of intra-abdominal infection demonstrate that uncontrolled infection with an implanted mix of aerobes and anaerobes leads to a two-stage (biphasic) infectious process. There is an early peritonitis phase with a high mortality rate and isolation of *E. coli* from blood and a late abscess formation phase in all survivors with isolation of anaerobes such as *B. fragilis* and *Fusobacterium varium*. These experiments and others support the concept that aerobic enteric organisms and anaerobes are pathogens in intra-abdominal infections. Aerobic bacteria, particularly *E. coli*, appear responsible for the early mortality from peritonitis, whereas anaerobic bacteria are major pathogens in abscesses, with *B. fragilis* predominating.[36]

Enterococcus can be isolated from many intra-abdominal infections in humans, but its role as a pathogen is not clear. Enterococcal infection occurs more commonly in postoperative peritonitis, in the presence of specific risk factors indicating failure of the host's defenses (immunocompromised patients), or with the use of broad-spectrum antibiotics.[37,38]

CLINICAL PRESENTATION

Intra-abdominal infections have a wide spectrum of clinical features often depending on the specific disease process, the location and magnitude of bacterial contamination, and concurrent host factors. Peritonitis is usually recognized easily, but intra-abdominal abscesses may often continue for considerable periods of time, either going unrecognized or being attributed to an unrelated disease process. Patients with primary and secondary peritonitis present quite differently (Table 137-4).[4,5,19,39-41]

TABLE 137-4

Clinical Presentation of Peritonitis

Primary Peritonitis

General

- The patient may not be in acute distress, particularly with peritoneal dialysis

Signs and symptoms

- The patient may complain of loss of appetite, bloating, nausea, vomiting (sometimes with diarrhea), and abdominal tenderness
- Temperature may be only mildly elevated or not elevated in patients undergoing peritoneal dialysis
- Bowel sounds are hypoactive
- The cirrhotic patient may have worsening encephalopathy
- Cloudy dialysate fluid with peritoneal dialysis

Laboratory tests

- The patient's WBC count may be only mildly elevated
- Ascitic fluid usually contains greater than 250 leukocytes/mm^3 (0.25 × 10^9/L), and bacteria may be evident on Gram stain of a centrifuged specimen
- In 60%-80% of patients with cirrhotic ascites, the Gram stain is negative

Other diagnostic tests

- Culture of peritoneal dialysate or ascitic fluid is typically positive, particularly if collected prior to initiation of antibiotics
- In conjunction with clinical findings, procalcitonin may be helpful for limiting duration of antibiotic therapy in secondary and tertiary peritonitis

Secondary Peritonitis

Signs and symptoms

- Generalized abdominal pain
- Tachypnea
- Tachycardia
- Nausea and vomiting
- Temperature is normal initially then increases to 37.8-38.9°C (100-102°F) within the first few hours and may continue to rise for the next several hours
- Hypotension, hypoperfusion, and shock if volume is not restored
- Decreased urine output due to vascular volume depletion

Physical examination

- Voluntary abdominal guarding changing to involuntary guarding and a "board-like abdomen"
- Abdominal tenderness and distension
- Faint bowel sounds that cease over time

Laboratory tests

- Leukocytosis (15,000-20,000 WBC/mm^3 [15 × 10^9 to 20 × 10^9/L]), with neutrophils predominating and an elevated percentage of immature neutrophils (bands)
- Elevated hematocrit and blood urea nitrogen because of dehydration
- Patient progresses from early alkalosis because of hyperventilation and vomiting to metabolic acidosis

Other diagnostic tests

- Abdominal radiographs may be useful because free air in the abdomen (indicating intestinal perforation) or distension of the small or large bowel is often evident

WBC, white blood cell.

Primary peritonitis can develop over a period of days to weeks and is usually a more indolent process than secondary peritonitis. The first sign of peritonitis may be a cloudy dialysate in patients undergoing peritoneal dialysis or worsening encephalopathy in a cirrhotic patient.

The patient with generalized bacterial peritonitis presents most often in acute distress. The patient lies still, usually on his or her back, possibly with the hips slightly flexed. Any movement of the patient, including rocking the bed or breathing, worsens the generalized abdominal pain.

If peritonitis continues untreated, the patient may experience hypovolemic shock from third-space fluid loss into the peritoneum, bowel wall, and lumen. This may be accompanied by sepsis because the inflamed peritoneum absorbs bacteria and toxins into mesenteric blood vessels and lymph nodes, initiating production of inflammatory cytokines. Hypovolemic shock is the major factor contributing to mortality in the early stage of peritonitis.

Intra-abdominal abscesses may pose a difficult diagnostic challenge because the symptoms are neither specific nor dramatic. The patient may complain of abdominal pain or discomfort, but these symptoms are not reliable. Fever is usually present; often it is low grade, but it may be high, with a spiking pattern. The patient may have a paralytic ileus and abdominal distension. The abdominal examination is unreliable; tenderness and pain may be present, and a mass may be palpated.

Peritonitis may result from an abscess that ruptures, spreading bacteria and toxins throughout the peritoneum. In other patients, the entry of bacterial toxins into the systemic circulation from the abscess may lead to sepsis and progressive multisystem organ failure (eg, renal, hepatic, pulmonary, or cardiovascular).

Laboratory studies are not generally helpful in the diagnosis of intra-abdominal abscesses, although most patients will have leukocytosis. C-reactive protein has been suggested, but due to its lack of specificity, it is not very useful. Procalcitonin has been postulated to be of use, but its exact utility still must be determined. Some patients may have positive blood cultures, whereas others, particularly patients with diabetes, may have hyperglycemia. The finding of *Bacteroides* or enteric bacteria in the bloodstream is often indicative of an intra-abdominal infectious process.

Radiographic methods are used to make the diagnosis of an intra-abdominal abscess. Plain radiographs may show air–fluid levels or a shift of normal intra-abdominal contents by the abscess mass. GI contrast studies may also demonstrate this displacement of abdominal structures. Both of these modalities provide indirect evidence of abscess presence but are not generally helpful in precisely locating the abscess.

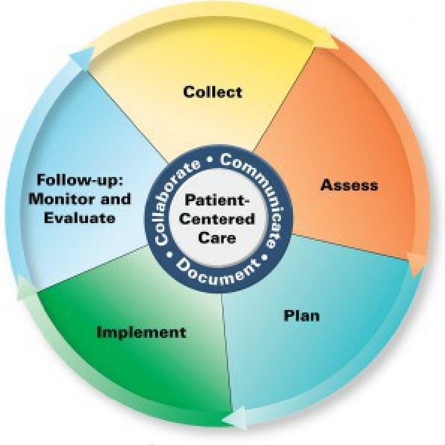
Ultrasound is the primary diagnostic method used when an intra-abdominal abscess is suspected. The procedure may be done at the bedside, which is particularly helpful when the patient is in the intensive care unit.

Computed tomography (CT) scanning is the preferred modality used to evaluate the abdomen for the presence of an abscess and is the imaging study of greatest value. If not contraindicated, an oral radiocontrast agent should be given to allow differentiation of the abscess from the bowel. IV radiocontrast material will be taken up preferentially in the wall of the abscess, creating a unique radiographic appearance, so-called rim enhancement. Magnetic resonance imaging offers no significant advantage when compared with CT scanning.

Intra-abdominal infection caused by disease processes at specific sites often produces characteristic manifestations that are helpful in diagnosis. For example, a patient with diverticulitis may exhibit stabbing left-lower-quadrant abdominal pain and constipation. Fever and leukocytosis are frequently present, and a tender mass is sometimes palpable. With appendicitis, the findings may be inconsistent, but many patients have a sudden onset of periumbilical or epigastric pain that is usually colicky and later shifts to the right lower quadrant. The location of pain may vary because the appendix can be in many locations (eg, retrocecal or pelvic) in the abdomen. A mass may be palpable on abdominal, pelvic, or rectal examination. The patient's temperature is generally mildly elevated early and then increases. If perforation and peritonitis occur, findings would include diffuse abdominal pain, rigidity, and sustained fever. More often, however, appendiceal perforation results in a local abscess.

PATIENT CARE PROCESS

Patient Care Process for Treatment of Intra-Abdominal Infections



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, weight, body mass index)
- Patient history (past medical, family, social—dietary habits, tobacco use, alcohol use, substance abuse) and surgical operations (site, date, procedure)
- Medication history at hospital admission (prescription and non-non-prescription medications and supplements), drug allergies, and intolerances; previous antibiotic use, inpatient and outpatient, dose and duration
- Microbiologic results from blood, intra-abdominal fluids, and other sources, and obtain susceptibility results when they are available
- Laboratory results for infection, major organ function (particularly kidney and liver), and immune status

Assess

- Hemodynamic status (eg, MAP, HR)
- Estimate creatinine clearance for drug dosing
- Review all culture results and consider anaerobic bacteria even though they may not be isolated in cultures

Plan*

- Determine initial empiric treatment and monitoring plan
- Establish antimicrobial monitoring goals for microbiologic and clinical outcomes
- Consider other medications that may be needed during treatment or post-surgery (ie, fluids, analgesics, medications for nausea and vomiting, thrombosis prevention)
- Check for drug interactions and dose adjustments based on end-organ function

Implement

- Initiate an empiric antimicrobial regimen, modify therapy once microbiologic data is available, and establish a tentative stop date
- De-escalate antimicrobial therapy as appropriate based on response and microbiologic data
- Discontinue adjunct medications when not needed or indicated
- Assess patient as needed for response to surgical control, medications, and other treatments

- Use measures to minimize adverse events to medications and assess for occurrence of adverse events
- Assess pain control and progress of gastrointestinal function
- Change to oral medications when appropriate after patient resumes oral feeding

Follow-up: Monitor and Evaluate

- Determine whether patient shows improvement with signs and symptoms of infection within 2 to 3 days after antimicrobials are initiated and surgical source control is completed
- The patient should be reassessed continually to determine the success or failure of therapies
- Monitor for emergence of resistant bacterial isolates in blood or other sources and change antimicrobials if needed
- Monitor for occurrence of secondary infections such as respiratory and urinary tract
- Upon hospital discharge, determine which medications the patient should be discharged with and provide counseling; discontinue unnecessary medications

Collaborate with patient, caregiver(s), and other healthcare professionals.

TREATMENT

Desired Outcome

The primary goals of treatment are correction of the intra-abdominal disease processes or injuries that have caused infection and the drainage of purulent collections (abscesses). A secondary objective is to achieve a resolution of infection without major organ system complications (pulmonary, hepatic, cardiovascular, or renal failure) or adverse drug effects. Ideally, the patient should be discharged from the hospital after treatment with full function for self-care and routine daily activities.

General Approach to Treatment

The treatment of intra-abdominal infection most often requires hospitalization and the coordinated use of three major modalities: (a) prompt surgical control and drainage of the infected site, (b) hemodynamic resuscitation and support of vital organ functions, and (c) early administration of appropriate antimicrobial therapy to treat infection not eradicated by surgery.[16]

Antimicrobials are an important adjunct to drainage procedures in the treatment of secondary intra-abdominal infections; however, the use of antimicrobial agents without surgical source control is usually inadequate. For most cases of primary peritonitis, drainage procedures may not be required, and antimicrobial agents become the mainstay of therapy.

④ In the early phase of serious intra-abdominal infections, attention should be given to the maintenance of organ system functions. With generalized peritonitis, initial large volumes of IV fluids are required to restore vascular volume, to improve cardiovascular function, and to maintain adequate tissue perfusion and oxygenation. Adequate urine output should be maintained to ensure adequate resuscitation and proper renal function. Respiratory function can be assisted by a variety of methods, including oxygen therapy, pulmonary physiotherapy, and ventilatory support in severely ill patients. Often the critically ill patient with intra-abdominal infection will require intensive care management, particularly if there is cardiovascular or respiratory instability. In addition, isolation procedures may be required if the infectious process poses a threat to other hospitalized patients.

An important component of therapy is nutrition. Intra-abdominal infections often involve the GI tract or disrupt its function (ie, paralytic ileus). The return of GI motility may take days, weeks, and, occasionally, months. In the interim, enteral or parenteral nutrition, as indicated, facilitates improved immune function and wound healing to ensure recovery. Additional information pertaining to enteral and parenteral nutrition can be found elsewhere in this book (Chapters 165 and 166).

Nonpharmacologic Treatment

Drainage Procedures

Primary peritonitis is treated with antimicrobials and rarely requires drainage. Secondary peritonitis requires surgical correction of the underlying pathology. The drainage of the purulent material is the critical component of management of an intra-abdominal abscess. Without adequate drainage of the abscess, antimicrobial therapy and fluid resuscitation can be expected to fail.

Secondary peritonitis is treated surgically; this is often called *source control*, which refers to all the physical measures undertaken to eradicate the focus of infection.[5,16] At the time of laparotomy (surgical opening and exploration of the abdomen), attempts are made to correct the cause of the peritonitis. This may include patching a perforated ulcer with omentum, removal of a segment of perforated colon, or excision of a portion of gangrenous small intestine. In addition, the surgeon may elect to leave the abdomen open after the laparotomy, plan a re-laparotomy at a later time regardless of the patient's condition, or perform re-laparotomy if the patient develops reinfection.[5,16] The goal of all these procedures is to repair or remove the inflamed or gangrenous tissue and to prevent further bacterial contamination. The presence of active inflammation increases the difficulty of the surgical procedure, which results in a higher morbidity and mortality rate than if the same procedures were performed in an elective setting without inflammation. Electing to leave the abdomen open after surgery is usually to prevent abdominal compartment syndrome; however, this is unnecessary when fluid collections can be removed with percutaneous catheter drainage.[42]

The presence of active inflammation may make it technically impossible to perform the definitive surgical procedure. In this situation, attempts are made to provide drainage of the infected or gangrenous structures. If an intra-abdominal abscess, separate from any intra-abdominal organ, is discovered during an exploratory laparotomy, it may be debrided, excised, or drained. If the intra-abdominal abscess involves an abdominal structure, then a resection of part or of the entire organ may be required. An example of this situation is an abscess associated with diverticular disease of the colon. Management may include drainage of the abscess and resection of the involved part of the colon. All foreign material, necrotic tissue, feces, blood, or purulent material should be removed from the operative field, and the peritoneum should be copiously irrigated with 0.9% sodium chloride to decrease the concentrations of bacteria or other noxious substances.

After an abscess is located, it must be drained. This may be performed surgically or with percutaneous, image-guided techniques.[5,16,43] Typically, image-guided techniques use ultrasonography or CT scanning. The management of an intra-abdominal abscess with percutaneous catheter drainage may be sufficient to resolve the infection. Some patients may require a subsequent procedure to treat the underlying GI conditions; however, a significant advantage is obtained by first draining the abscess percutaneously. This allows the surgical procedure to be performed on a patient who is no longer suffering from the systemic manifestations of uncontrolled infection. Drainage techniques may be performed using endoscopy or laparoscopy. These minimal-access techniques may offer advantages when compared with traditional surgery but will probably be used less often than radiologically assisted percutaneous drainage techniques.

The most valuable microbiologic information may be obtained at the time of percutaneous or operative abscess drainage. If purulent material or presumably infected fluid is found, it is best to aspirate 2 to 3 mL into a syringe, remove any air, and tightly cap the syringe. The specimen should be promptly delivered to the microbiology laboratory, where a Gram stain should be performed immediately, and cultures prepared for identification of aerobic and anaerobic bacteria. If no fluid is available for collection, culture swab devices may be applied to the infected area; however, anaerobic organisms often are not isolated from swabs.

Fluid Therapy

④ Patients should be evaluated for signs of hypovolemia, hypoperfusion, and shock. Initial effective fluid repletion and management are required for successful management of intra-abdominal infections. Fluid therapy is instituted for the purposes of achieving or maintaining intravascular volume to ensure adequate cardiac output, tissue perfusion, and correction of acidosis. Loss of fluid through vomiting, diarrhea, or nasogastric suction contributes to fluid depletion. A more thorough discussion of sepsis and septic shock, including fluid resuscitation, is presented elsewhere in this book (Chapters e42 and 142).

In patients with peritonitis, hypovolemia is often accompanied by metabolic acidosis. Although serum lactate is not a direct measure of tissue perfusion, it may serve as a surrogate marker representing tissue hypoxia and is therefore recommended by the Surviving Sepsis Campaign 2021 update to guide fluid administration. In those patients with sepsis hypoperfusion or septic shock, IV fluids should consist of a 30 mL/kg bolus of crystalloids with additional fluids targeting predefined therapeutic goals.[44-46] Initial fluid resuscitation should be completed within 3 hours of hypoperfusion recognition. Thereafter, fluids may be required at a rate of 1 L/hr or higher. Once targeted therapeutic goals are reached, judicious use of fluids should be used, as a sustained positive fluid balance after initial resuscitation may be harmful.[16,47] Maintenance fluids should be instituted with 0.9% sodium chloride, 5% dextrose, and 0.45% sodium chloride, or a balanced crystalloid solution.[48] The administration rate should be based on estimated daily fluid loss through urine and nasogastric suction, including 0.5 to 1 L for insensible fluid loss. Potassium can be included in maintenance fluids if the patient is experiencing vomiting, diarrhea, or has nasogastric suction.

Pharmacologic Treatment

Antimicrobial Therapy

The goals of antimicrobial therapy are: (a) to eliminate the intra-abdominal infection and prevent the establishment of metastatic foci of infection or bacteremia, (b) to reduce suppurative complications (eg, abscess formation) after bacterial contamination, and (c) to prevent local spread of existing infection. After suppuration has occurred, a cure by antibiotic therapy alone is very difficult to achieve; antimicrobials may serve to improve the results obtained with surgery.

⑤ An empirical antimicrobial regimen should be started as soon as the presence of intra-abdominal infection is suspected. The Surviving Sepsis Campaign Guidelines recommend that antimicrobial therapy is administered immediately and within 1 hour of the recognition of sepsis or septic shock.[46] Therapy must be initiated based on the likely pathogens, potential resistance, and severity of patient illness. Resistance is common among gram-negative pathogens to fluoroquinolones and ampicillin/sulbactam; this emphasizes the importance of using local susceptibility data to guide empiric therapy and tailoring the antibiotic regimen based on susceptibility results.[49] Predominant pathogens, as discussed in the preceding section, vary depending on the site of intra-abdominal infection and the underlying disease process. Table 137-5 lists the likely pathogens against which antimicrobial agents should be directed.

TABLE 137-5

Likely Intra-Abdominal Pathogens

Type of Infection	Aerobes	Anaerobes
Primary (Spontaneous) Bacterial Peritonitis		
Children	Group A *Streptococcus*, *E. coli*, pneumococci	—
Cirrhosis	*E. coli*, *Klebsiella*, pneumococci (many others)	—
Peritoneal dialysis	*Staphylococcus*, *Streptococcus*, *E. coli*, *Klebsiella*, *Pseudomonas*	—
Secondary Bacterial Peritonitis		
Gastroduodenal	*Streptococcus*, *E. coli*	—
Biliary tract	*E. coli*, *Klebsiella*, enterococci	*Clostridium* or *Bacteroides* (infrequent)
Small or large bowel	*E. coli*, *Klebsiella*, *Proteus*	*B. fragilis* and other *Bacteroides*, *Clostridium*
Appendicitis	*E. coli*, *Pseudomonas*	*Bacteroides*
Abscesses	*E. coli*, *Klebsiella*, *Streptococcus*, enterococci	*B. fragilis* and other *Bacteroides*, *Clostridium*, anaerobic cocci
Liver	*E. coli*, *Klebsiella*, *Streptococcus*, enterococci, *Staphylococcus*, amoeba	*Bacteroides* (infrequent)
Spleen	*Staphylococcus*, *Streptococcus*, *E. coli*, *Salmonella*	

Antimicrobial Experience

Many studies have been conducted evaluating or comparing the effectiveness of antimicrobials for the treatment of intra-abdominal infections. Substantial differences in patient outcomes between specific agents have not generally been demonstrated.[50]

Important findings from over 20 years of clinical trials regarding selection of antimicrobials for intra-abdominal infections are the following:

1. Antimicrobial regimens used for secondary infections should cover a broad spectrum of aerobic and anaerobic bacteria from the GI tract. The local epidemiology of resistant pathogens, patient-specific risk factors for resistant pathogens, and patient severity of illness should guide empiric treatment.
2. Resistance is prevalent among *B. fragilis* to clindamycin and Enterobacterales to ampicillin/sulbactam and quinolones, and therefore these agents should not be routinely used empirically for complicated intra-abdominal infections.[51,52]
3. If the causative pathogens are susceptible and the patient has clinically responded, antimicrobial treatment can be completed orally with amoxicillin/clavulanate, metronidazole with either ciprofloxacin or levofloxacin, or moxifloxacin.[53]
4. Four days of antimicrobial treatment after adequate source control is sufficient for most intra-abdominal infections.[16,54,55]

Intra-abdominal infections present in many different ways and with a wide spectrum of severity. The regimen employed and duration of treatment depends on the specific clinical circumstances (ie, the nature of the underlying disease process, severity of illness, and risk of resistant pathogens).

Recommendations

⑥ For most intra-abdominal infections, the antimicrobial regimen should be effective against both aerobic and anaerobic bacteria.[55,56] When initial antimicrobial therapy is inactive, morbidity and mortality rates are higher than when initially active therapy is used.[55] Generally, agents with activity against enteric gram-negative bacilli, such as *E. coli* and *Klebsiella* spp., and anaerobes, including *B. fragilis,* should be administered. If most of the organisms can be eliminated through drainage or antimicrobials, the synergistic effect may be removed, and the patient’s defenses may be able to resolve the remaining infection.

Table 137-6 lists the agents recommended by the Infectious Diseases Society of America (IDSA) and the Surgical Infection Society (SIS) for the treatment of community-acquired complicated intra-abdominal infections.[16,55] These recommendations were formulated using an evidence-based approach. Table 137-7 lists additional evidence-based recommendations for the treatment of complicated intra-abdominal infections. Choosing empiric antibiotic therapy based on these recommendations within the IDSA/SIS guidelines has been associated with a decreased time to active therapy for patients with community-onset complicated intra-abdominal infection.[57] Although most community-acquired infections are of mild-to-moderate severity, healthcare-associated infections tend to be more severe, more difficult to treat, and more common due to resistant pathogens. Table 137-8 presents guidelines for treatment and alternative regimens for specific situations. These are general guidelines; such a table cannot incorporate many factors, including local resistance patterns to commonly used agents such as quinolones.

TABLE 137-6

Recommended Agents for the Treatment of Community-Acquired Complicated Intra-Abdominal Infections in Adults

Agents Recommended for Mild-to-Moderate Infections	Agents Recommended for High Severity Infections
Single Agent	
Cefoxitin[a]	Piperacillin/tazobactam
Moxifloxacin[b]	Imipenem/cilastatin,[c] meropenem,[c] meropenem/vaborbactam,[d] imipenem/relebactam[d]
Ertapenem[c]	
Eravacycline[d]	
Combination Regimens	
Cefazolin,[a] cefuroxime,[a] ceftriaxone, or cefotaxime each in combination with metronidazole	Cefepime, ceftazidime, cefiderocol,d ceftazidime/avibactam,[d] or ceftolozane/tazobactam[d] each in combination with metronidazole
Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole	Ciprofloxacin[b] or levofloxacin[b] each in combination with metronidazole

[a] Empiric first- and second-generation cephalosporin use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b] Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

[c] Carbapenems should be reserved for settings where there is a high risk of resistance to other agents (ie, extended-spectrum β-lactamase [ESBL]-producing pathogens).

[d] These broad-spectrum agents should be reserved for patients infected with Enterobacterales that are resistant to all other β-lactams. Ceftazidime/avibactam, meropenem/vaborbactam, and imipenem/relebactam are preferred for KPC-producing pathogens. Ceftolozane/tazobactam may have activity against multidrug-resistant *Pseudomonas*; however, susceptibility must be confirmed.

Data from References 16,55,58, and 59.

TABLE 137-7

Evidence-Based Recommendations for Treatment of Complicated Intra-Abdominal Infections

	Grade of Recommendation[a]
Elements of Appropriate Intervention	
An appropriate source control procedure to drain infected foci, control ongoing peritoneal contamination by diversion or resection, and restore anatomic and physiological function to the extent feasible is recommended for nearly all patients with	B-2

intra-abdominal infections	
Community-Acquired Infections of Mild-to-Moderate Severity in Adults	
Antibiotics used for empiric treatment of community-acquired intra-abdominal infections should be active against enteric gram-negative aerobic and facultative bacilli and enteric gram-positive streptococci	A-1
For patients with mild-to-moderate, community-acquired infections, regimens with substantial anti-pseudomonal activity are not required (Table 137-6)	A-1
Empiric coverage of *Enterococcus* is not necessary in patients with mild-to-moderate community-acquired intra-abdominal infection	A-1
The use of agents listed as appropriate for high-severity, community-acquired infection and healthcare-associated infection is not recommended for patients with mild-to-moderate, community-acquired infection, because such regimens may carry a greater risk of toxicity and facilitate acquisition of more resistant organisms	B-2
High-Severity, Community-Acquired Infections in Adults[b]	
The empiric use of antimicrobial regimens with broad-spectrum activity against gram-negative organisms including *Pseudomonas* spp., such as meropenem, imipenem/cilastatin, piperacillin–tazobactam, ciprofloxacin or levofloxacin in combination with metronidazole, or ceftazidime or cefepime in combination with metronidazole, is recommended for patients with high-severity, community-acquired intra-abdominal infection (Table 137-6)	A-1
Aztreonam plus metronidazole is an alternative, but addition of an agent effective against gram-positive cocci is recommended	B-3
Healthcare-Associated Infections in Adults[c]	
Empiric antibiotic therapy for healthcare-associated intra-abdominal infections should be driven by local microbiologic results	A-2
To achieve empiric coverage of likely pathogens, multidrug regimens that include agents with expanded spectra of activity against gram-negative aerobic and facultative bacilli may be needed. These agents include meropenem, imipenem/cilastatin, piperacillin/tazobactam, or metronidazole combined with either cefepime or ceftazidime. For multidrug-resistant aerobic gram-negative pathogens, aminoglycosides, colistin, polymyxin B, meropenem/vaborbactam, imipenem/relebactam, eravacycline, cefiderocol, ceftazidime/avibactam, or ceftolozane/tazobactam may be required	B-3
Antimicrobial Agents Not Recommended	
Ampicillin/sulbactam is not recommended for use because of high rates of resistance to this agent among community-acquired *E. coli*	B-2
Quinolone-resistant *E. coli* have become common in some communities, and quinolones should not be used unless hospital surveys indicate 90% susceptibility of *E. coli* to quinolones	A-2
Clindamycin is not recommended for use because of increasing prevalence of resistance to these agents among *Bacteroides fragilis*	B-2
Because of the availability of less toxic agents demonstrated to be at least equally effective, aminoglycosides are not recommended for routine use in adults with community-acquired intra-abdominal infections	B-2
Oral Completion Therapy	

For adults recovering from an intra-abdominal infection, completion of the antimicrobial course with oral forms of moxifloxacin, ciprofloxacin plus metronidazole, levofloxacin plus metronidazole, an oral cephalosporin with metronidazole, or amoxicillin/clavulanic acid is acceptable in patients able to tolerate an oral diet and in patients in whom susceptibility studies do not demonstrate resistance	B-2
Duration of Therapy	
Antimicrobial therapy of established infection should be limited to 4 days, unless it is difficult to achieve adequate source control. Longer durations of therapy have not been associated with improved outcome	A-1
For acute stomach and proximal jejunum perforations, in the absence of acid-reducing therapy or malignancy and when source control is achieved within 24 hours, prophylactic anti-infective therapy directed at aerobic gram-positive cocci for 24 hours is adequate	B-2
Bowel injuries attributable to penetrating, blunt, or iatrogenic trauma that are repaired within 12 hours and any other intraoperative contamination of the operative field by enteric contents should be treated with antibiotics for ≤24 hours	A-1
Acute appendicitis without evidence of perforation, abscess, or local peritonitis requires only prophylactic administration of narrow spectrum regimens active against aerobic and facultative and obligate anaerobes; treatment should be discontinued within 24 hours	A-1
The administration of prophylactic antibiotics to patients with severe necrotizing pancreatitis prior to the diagnosis of infection is not recommended	A-1
Anaerobic Coverage	
Coverage for obligate anaerobic bacilli should be provided for distal small bowel, appendiceal, and colon-derived infection and for more proximal GI perforations in the presence of obstruction or paralytic ileus	A-1
Antifungal Therapy	
Antifungal therapy for patients with high-severity community-acquired or healthcare-associated infection is recommended if *Candida* is grown from intra-abdominal cultures	B-2
Anti-MRSA Therapy	
Empiric antimicrobial coverage directed against MRSA should be provided to patients with healthcare-associated intra-abdominal infection who are known to be colonized with the organism or who are at risk of having an infection due to this organism because of prior treatment failure and significant antibiotic exposure	B-2
Vancomycin is recommended for treatment of suspected or proven intra-abdominal infection due to MRSA	A-3
Antienterococcal Therapy	
Antimicrobial therapy for enterococci should be given when enterococci are recovered from patients with high-severity community-acquired or healthcare-associated infection	B-III
Empiric antienterococcal therapy is recommended for patients with high-severity community-acquired infections and healthcare-associated intra-abdominal infections, particularly those with postoperative infection, those who have previously received cephalosporins or other antimicrobial agents selected for *Enterococcus* species, immunocompromised patients, and those with	B-II

valvular heart disease or prosthetic intravascular materials	
Initial empiric antienterococcal therapy should be directed against *Enterococcus faecalis*. Antibiotics that can potentially be used against this organism, on the basis of susceptibility testing of the individual isolate, include ampicillin, ampicillin/sulbactam, piperacillin/tazobactam, imipenem/cilastatin, and vancomycin	B-III
Empiric therapy directed against vancomycin-resistant *Enterococcus faecium* is not recommended unless the patient is at very high risk for an infection due to this organism, such as a liver transplant recipient with an intra-abdominal infection originating in the hepatobiliary tree or a patient known to be colonized with vancomycin-resistant *E. faecium*	B-III

[a] Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from ≥1 properly randomized, controlled trial. 2 = Evidence from ≥1 well-designed clinical trial without randomization, from cohort or case-controlled analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

[b] Criteria for high-severity community-acquired infection: sepsis or septic shock, APACHE II score ≥15, delay in initial intervention >24 hours, advanced age, comorbidity and degree of organ dysfunction, low albumin level, poor nutritional status, degree of peritoneal involvement or diffuse peritonitis, inability to achieve adequate debridement or control of drainage, and presence of malignancy.

[c] Criteria for classification of intra-abdominal infections as healthcare-associated infection vary. However, patients who develop an infection after surgery, reside in a long-term care facility, who were recently hospitalized, or who have other significant healthcare exposure can be considered to have a healthcare-associated intra-abdominal infection.

MRSA, methicillin-resistant *Staphylococcus aureus*.

Data from References 16,55, and 58.

TABLE 137-8

Guidelines for Empiric Antimicrobial Agents for Intra-Abdominal Infections

	Primary Agents	Alternatives
Primary (Spontaneous) Bacterial Peritonitis		
Cirrhosis	Ceftriaxone, cefotaxime	1. Piperacillin/tazobactam, carbapenems 2. Aztreonam combined with an agent active against *Streptococcus* spp. (eg, vancomycin) or quinolones with significant *Streptococcus* spp. activity (levofloxacin, moxifloxacin)
Peritoneal dialysis	Initial empiric regimens should be active against both gram-positive (including *S. aureus*) and gram-negative pathogens: gram-positive agent (first-generation cephalosporin or vancomycin) plus a gram-negative agent (third-generation cephalosporin or aminoglycoside)	1. Cefepime or carbapenems may be used alone 2. Aztreonam or an aminoglycoside may be used in place of ceftazidime or cefepime as long as combined with a gram-positive agent 3. Quinolones may be used in place of gram-negative agents if local susceptibilities allow
	1. *Staphylococcus* spp.: oxacillin/nafcillin or first-generation cephalosporin	1. Vancomycin should be used for methicillin-resistant *Staphylococcus* spp.

		2. May consider addition of rifampin for 5-7 days with vancomycin
	2. *Streptococcus* or *Enterococcus*: ampicillin	1. Daptomycin or linezolid should ideally be used to treat vancomycin-resistant *Enterococcus* spp. not susceptible to ampicillin
	3. Aerobic gram-negative bacilli: ceftazidime or cefepime	1. The regimen should be based on in vitro sensitivity tests
	4. *Pseudomonas aeruginosa*: two agents with differing mechanisms of action, such as an intraperitoneal ceftazidime or cefepime each combined with either tobramycin or oral ciprofloxacin	
Secondary Bacterial Peritonitis		
Perforated peptic ulcer	First-generation cephalosporins	1. Ceftriaxone, cefotaxime, or antianaerobic cephalosporins[a]
Other	Third- or fourth-generation cephalosporin with metronidazole, piperacillin–tazobactam or carbapenem	1. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin[b] alone 2. Aztreonam with vancomycin and metronidazole 3. Antianaerobic cephalosporins[a]
Abscess		
General	Third- or fourth-generation cephalosporin with metronidazole or piperacillin/tazobactam	1. Imipenem/cilastatin, meropenem, or ertapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone
Liver	As above	Use metronidazole if amoebic liver abscess is suspected
Spleen	Ceftriaxone or cefotaxime	Moxifloxacin[b] or levofloxacin[b]
Other Intra-Abdominal Infections		
Appendicitis	Same management as for community-acquired complicated intra-abdominal infections as listed in Table 137-6[44]	
Community-acquired acute cholecystitis	Ceftriaxone or cefotaxime	Severe infection, piperacillin/tazobactam, antipseudomonal carbapenem, aztreonam with metronidazole
Cholangitis	Ceftriaxone or cefotaxime each with or without metronidazole	Vancomycin with aztreonam with or without metronidazole

Acute contamination from abdominal trauma	Antianaerobic cephalosporins[a] or metronidazole with either ceftriaxone or cefotaxime	1. Piperacillin/tazobactam or a carbapenem 2. Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone
Diverticulitis	Cefazolin, cefuroxime, or ceftriaxone with metronidazole or ampicillin/sulbactam	Ciprofloxacin[b] or levofloxacin[b] each with metronidazole or moxifloxacin alone

[a]Cefoxitin or ceftizoxime; these agents should be avoided empirically unless local antibiograms show >80% to 90% susceptibility of *E. coli* to these agents.

[b]Use of quinolones may be associated with treatment failure due to increasing resistance of enteric pathogens including *E. coli*. Empiric quinolone use should be avoided unless local antibiograms show >80% to 90% susceptibility of *E. coli* to quinolones.

Data from References 55 and 60.

Most patients with severe intra-abdominal infection, sepsis, or healthcare-associated infection should be placed on piperacillin/tazobactam, cefepime with metronidazole, or a carbapenem with *Pseudomonas* activity such as imipenem, or meropenem. In patients with IgE-mediated allergic reactions to β-lactams (hives/urticaria, bronchospasm, angioedema, or anaphylaxis), a combination therapy with aztreonam, vancomycin, and metronidazole may be used. The benefits of systemic preemptive antifungal therapy (with fluconazole or an echinocandin) as a means to prevent invasive candidiasis in patients with intra-abdominal infection have not been established.[61] However, patients with intra-abdominal infections are often at high risk for systemic candidiasis, given multiple risk factors may be present such as recent abdominal surgery, the presence of a central line, parenteral nutrition, and broad-spectrum antibiotic use.[16,55,62] When invasive candidiasis is suspected, generally an echinocandin should be used empirically because these patients are often severely ill and may be at risk for infection with a fluconazole-resistant *Candida* species.[62] As noted in Table 137-7, *Candida* should be treated if isolated from cultures in patients with high-severity, community-acquired or healthcare-associated infection.[16,62] If the *Candida* spp. is fluconazole susceptible and the patient is clinically improving, it is reasonable to de-escalate from an echinocandin to fluconazole.

Aminoglycoside-based treatment regimens are not routinely recommended due to their narrow therapeutic index (nephrotoxicity, ototoxicity) relative to the recommended agents such as β-lactams.[63,64] Aminoglycosides are reserved primarily for infections due to presumed or proven multidrug-resistant pathogen(s).[50,55]

If an aminoglycoside is required, the initial dosage should be determined based on the patient's weight and renal function. Traditionally, gentamicin and tobramycin were administered multiple times daily with specific peak (6-10 mcg/mL [mg/L; 13-21 μmol/L]) and trough (less than 1-2 mcg/mL [mg/L; less than 2-4 μmol/L]) serum concentration targets. Because aminoglycosides have concentration-dependent killing and have a relatively long postantibiotic effect for aerobic gram-negative bacilli, extended-interval dosing of aminoglycosides is possible. For most patients and indications, extended-interval aminoglycoside dosing (ie, 5-7 mg/kg once daily for tobramycin or gentamicin, 15-20 mg/kg once daily for amikacin) has replaced traditional dosing, given equivalent efficacy and decreased nephrotoxicity.[65-67]

Antimicrobial resistance continues to increase worldwide.[68-70] Enterobacterales producing extended-spectrum β-lactamases (ESBL) have been increasingly isolated from intra-abdominal cultures.[49,51] For patients with ESBL-producing pathogens, carbapenems are typically the drugs of choice. With the increased use of carbapenems, pathogens have continued to evolve with the development of β-lactamases that hydrolyze carbapenems (eg, *Klebsiella pneumoniae* carbapenemase [KPC]), multidrug-resistant *Pseudomonas* spp., and carbapenem-resistant *Acinetobacter* spp. Especially in patients with healthcare-associated intra-abdominal infections, these multidrug-resistant pathogens have forced clinicians to use more toxic and potentially less effective agents such as the polymyxins, tigecycline, and aminoglycosides. For example, the product labeling for tigecycline carries a Black Box Warning, as it has been associated with an increased risk of mortality relative to comparator agents, which is based on pooled data collected from randomized controlled trials including patients with intra-abdominal infections, skin and skin structure infections, and ventilator-associated pneumonia.[71-73] Accordingly, the 2017 SIS guidelines recommend against the use of tigecycline except potentially as part of a combination regimen for multidrug-resistant pathogens.[16] Three potential therapeutic options for multidrug-resistant pathogens, ceftolozane/tazobactam, ceftazidime/avibactam, and eravacycline have been FDA-approved for the treatment of complicated intra-abdominal infections in combination with metronidazole.[66,67,74] Ceftolozane/tazobactam may be active against multidrug-resistant pathogens, particularly *Pseudomonas* spp., while ceftazidime/avibactam is active against KPC-producing Enterobacterales.

These agents may be more effective than colistin-based regimens for infections due to KPC-producing Enterobacterales.[59,75-77] However, it is not uncommon for organisms that are resistant to all other β-lactams to also be resistant to these three new agents, and so susceptibility must be confirmed. Despite this, these agents are highly valuable in terms of their activity against multidrug-resistant pathogens, and as such, their use should be reserved for patients with a suspected or confirmed infection due to a pathogen resistant to all other β-lactams. The limited safe-and-effective therapeutic options for resistant organisms highlight the need, from an individual patient and public health standpoint, for pharmacists and other clinicians to ensure that antimicrobials are selected appropriately, at the optimal dose, and for the correct duration.

With intra-abdominal contamination from the upper GI tract (perforation of a peptic ulcer or biliary tract disease), anaerobes such as *B. fragilis* are uncommon pathogens, and therefore other empiric agents such as ampicillin, penicillin, or first-generation cephalosporins are reasonable. Anaerobic coverage is also not necessary for primary peritonitis associated with cirrhosis, and cefotaxime or ceftriaxone remain the treatments of choice.[78]

Empiric coverage of *Enterococcus* in mild-to-moderate, community-acquired intra-abdominal infections is not recommended.[55] The failure of host defenses may be a critical factor in the pathogenicity of enterococci. In patients with high-severity, community-acquired intra-abdominal infections or patients with healthcare-associated infection, coverage of *Enterococcus faecalis* should be included in the initial regimen.[16,55] Ampicillin remains the drug of choice for this indication because it is active against the vast majority of *E. faecalis.* Notably, piperacillin/tazobactam and imipenem/cilastatin both have activity against ampicillin-susceptible *E. faecalis,* and therefore these may be elegant choices for empiric therapy of high-severity community-acquired or healthcare-associated intra-abdominal infections. Vancomycin may also be active against enterococci; however, rates of vancomycin-resistant enterococci are increasing, especially in select patient populations (eg, liver transplantation, immunocompromised patients).[79] Agents, including linezolid or daptomycin, are commonly used for vancomycin-resistant *Enterococcus* infections. Table 137-7 lists additional evidence-based recommendations for *Enterococcus* spp. coverage.

(7) Intraperitoneal administration of antibiotics is preferred over IV therapy in the treatment of peritonitis that occurs in patients undergoing CAPD.[60,80] The International Society of Peritoneal Dialysis guidelines for the diagnosis and pharmacotherapy of peritoneal dialysis-associated infections provide antimicrobial dosing recommendations based on the modality of dialysis (continuous or intermittent).[60]

Given the peritoneal catheter exit site and tunnel is frequently the source of peritoneal dialysis-related peritonitis, prophylaxis with topic antibiotic cream or ointment to the catheter exit site reduces infections caused by *S. aureus* and gram-negative bacilli, including *Pseudomonas* spp.[81] When infection occurs, antimicrobial agents effective against both gram-positive skin flora (including *S. aureus*) and gram-negative organisms should be used for initial intraperitoneal empiric therapy. The most important factors to take into consideration for initial antimicrobial selection are the dialysis center's and the patient's history of infecting organisms and their sensitivities. For empiric intraperitoneal therapy, cefazolin or vancomycin in cases of high prevalence of MRSA or β-lactam allergy may be used for gram-positive coverage. Glycopeptide-containing regimens (vancomycin) were more likely to achieve complete cure compared to first-generation cephalosporins.[80,82] When vancomycin is used, it is preferred that it be given intraperitoneally via intermittent dosing (15-30 mg/kg every 5-7 days) and serum concentrations should be maintained above 15 mcg/mL (mg/L; 10.4 μmol/L).[83] When administered via intermittent dosing, generally the antibiotic should dwell for at least 6 hours. One of these gram-positive agents should be combined with a gram-negative agent such as ceftazidime or an aminoglycoside. If an aminoglycoside is used, it is preferred that it be given intraperitoneally via intermittent dosing (eg, gentamicin 0.6 mg/kg/day). Long durations of aminoglycoside therapy should be avoided if possible to mitigate the risk of ototoxicity and loss of residual renal function. Another option is monotherapy with cefepime or imipenem/cilastatin. If patients have significant residual renal function, increased antimicrobial doses may not be necessary.[60,83] As with other intra-abdominal infections, source control should be prioritized; in patients with an ongoing catheter exit site or tunnel infection, catheter removal with reinsertion should be strongly considered. If peritonitis relapses or recurs, the catheter should be promptly removed. Antimicrobial therapy should typically be continued for 14 to 21 days. The reader is referred to recent guidelines for additional information.[60,81]

After acute bacterial contamination, such as with abdominal trauma where GI contents spill into the peritoneum, antibiotics should be administered. If the patient is seen soon after injury (within 2 hours) and surgical measures are instituted promptly, an anti-anaerobic cephalosporin (such as cefoxitin), a third-generation cephalosporin (such as ceftriaxone) with metronidazole, or piperacillin/tazobactam is effective in preventing most infectious complications. Antimicrobials should be administered as soon as possible after injury.[84]

8 For appendicitis, the antimicrobial regimen used should depend on the appearance of the appendix at the time of operation, which may be normal, inflamed, gangrenous, or perforated. It is advisable to begin antimicrobial agents before the appendectomy is performed. Reasonable regimens would be antianaerobic cephalosporins or, if the patient is seriously ill, piperacillin/tazobactam, or an anti-pseudomonal carbapenem. If, at operation, the appendix is normal or inflamed, postoperative antimicrobials are not required. If the appendix is gangrenous or perforated, a treatment course of 3 to 4 days with the agents listed in Table 137-6 is appropriate.[11,85] For uncomplicated appendicitis (defined as the absence of perforation, abscess, appendicolith, CT consistent with possible tumor, peritonitis, severe systemic illness) confirmed by CT, a nonsurgical approach of antibiotic therapy alone may also be considered.[11,86,87] Patients who received initial appendectomy (mostly open procedures), instead of antibiotics alone, experienced greater pain, a longer duration of sick leave from work, and more complications such as surgical site infections and delayed healing.[11] In addition, 27% of patients managed nonsurgically required an appendectomy within 1 year of their index hospitalization. In over 1,500 adults with appendicitis, antibiotics were found to be non-inferior to appendectomy at 30 days based on a quality of life questionaire.[87] However, complications were more common in the antibiotics groups and 29% required an appendectomy within 90 days. Similarly, a smaller randomized study also demonstrated that 27.3% of adult patients receiving antibiotics alone required an appendectomy within 1 year,[11] and 39.1% were at an increased risk of late recurrence of uncomplicated acute appendicitis within 5 years.[88] Conversely, another smaller randomized study found that adult patients who received a supportive care only for CT-confirmed uncomplicated appendicitis experienced similar treatment failure rates within 19 months compared to those who received 4 days of antibiotic therapy.[89] In children, nonoperative management of uncomplicated appendicitis with 7 days of antibiotics had a success rate of 67.1% and had significantly fewer disability days at 1 year compared to those who underwent surgery.[90] Despite these limitations, the risks and benefits of surgery versus antibiotics alone should be considered along with the patient's own preferences.

Treatment of diverticulitis varies based on disease severity. For mild, acute uncomplicated diverticulitis, antibiotics are not necessary with appropriate follow-up in immunocompetent adults[91]; however, if antibiotics are prescribed, amoxicillin/clavulanate or an oral cephalosporin with metronidazole is recommended.[92] Oral antibiotics (ciprofloxacin with metronidazole) are as effective as intravenous antibiotics for uncomplicated diverticulitis.[93] In adults who present with complicated diverticulitis with an abscess, antibiotics that cover gram-negative aerobic bacilli and anaerobes should be combined with drainage of the abscess; however, once source control is achieved, antibiotics are no longer needed. In immunocompromised adults, early elective resectional surgery is recommended due to the risk for early, frequent, and severe relapses of complicated acute diverticulitis managed with antibiotics alone. In general, 15% to 30% of patients admitted for management of acute diverticulitis required surgery during that admission.[94] When surgery is required, laparoscopic surgery is preferred to open colectomy due to shorter lengths of hospital stay, fewer complications, and lower in-hospital mortality.[95]

Acute intra-abdominal contamination, such as after a traumatic injury, may be treated with a short antimicrobial course (24 hours).[84] For established infections (ie, peritonitis or intra-abdominal abscess), an antimicrobial course limited to 4 days after source control is appropriate.[16,54] This allows eradication of bacteria remaining in the peritoneum after a surgical procedure that may enter the peritoneum through healing suture lines. Under certain conditions, therapy for longer than 4 days would be justified (eg, when the focus of infection in the abdomen is still present). For some abscesses, such as pyogenic liver abscess, antimicrobials may be required for a month or longer. If definitive source control is not possible, then a duration of 5 to 7 days of antibiotic therapy may be considered based on the patient's clinical stability including resolution or improvement in leukocytosis, fever, GI function.[16] These patients should be closely monitored for clinical worsening after cessation of antibiotics; a source control intervention may need to be reconsidered or antibiotics may need to be reinitiated.

Intraperitoneal irrigation of antimicrobial agents for the prevention of surgical site infection, abscess development, and other complications in patients with peritonitis has been studied; however, the quality of the data is limited and precludes a definitive determination of efficacy.[96,97] Possibly the most important aspect of peritoneal irrigation is the dilutional effect on bacteria and adjuvants that promote infection (intestinal contents and hemoglobin), and elimination of debris and gross contamination. Most systemically administered antimicrobials easily cross the peritoneal membrane so that peritoneal fluid concentrations are similar to serum. Confined areas, such as an abscess, can be expected to attain much lower antimicrobial concentrations. Given the unclear benefit of antibiotic irrigation, irrigation with crystalloid fluid alone is recommended.[16]

EVALUATION OF THERAPEUTIC OUTCOMES

Whichever antimicrobial regimen is chosen, the patient should be reassessed continually to determine the success or failure of therapies. The clinician should recognize that there are many reasons for poor patient outcomes with intra-abdominal infections, improper antimicrobial administration is only one. The patient may be immunocompromised, which decreases the likelihood of successful outcome with any regimen. There may be surgical reasons for poor patient outcome. Failure to identify all intra-abdominal foci of infection or leaks from a GI anastomosis may cause continued infection. Finally, antimicrobial resistance may contribute to treatment failure as isolates from intra-abdominal infections are increasingly drug resistant.[49,98]

The outcome from intra-abdominal infection is not determined solely by what transpires in the abdomen. Unsatisfactory outcomes in patients with intra-abdominal infections may result from complications that arise in other organ systems, including renal or respiratory failure. Furthermore, pneumonia is a complication that is commonly associated with mortality after intra-abdominal infection.[99] Other nosocomial infections including catheter-related bacteremia and urinary tract infection are also independent predictors of mortality in patients with intra-abdominal infections.[100]

⑨ Once antimicrobials are initiated and the other important therapies described earlier are used, most patients should show improvement within 2 to 3 days. Usually, temperature will return to near normal, vital signs should stabilize, and the patient should not appear in distress, with the exception of recognized discomfort and pain from incisions, drains, and the nasogastric tube. Within 24 to 72 hours, aerobic bacterial culture results should return. If a suspected pathogen is not sensitive to the antimicrobial agents being given, the regimen should be changed to active therapy. If the isolated pathogen is susceptible to a narrower spectrum agent, therapy should be de-escalated.

With anaerobic culturing techniques and the slow growth of these organisms, anaerobes are often not identified until 4 to 7 days after culture. A report indicating that anaerobes were not isolated should not be the sole justification for discontinuing antianaerobic drugs because anaerobic bacteria that were present in the infectious process may not have been collected or maintained in anaerobic conditions which can lead to cell death in vitro.

Reasons for antimicrobial failure may not always be apparent. Even when antimicrobial susceptibility tests indicate that an organism is susceptible in vitro to the antimicrobial agent, therapeutic failures may occur. Possibly there is poor penetration of the antimicrobial agent into the focus of infection, or bacterial resistance may develop after initiation of antimicrobial therapy. In addition, it is possible that an antimicrobial regimen may encourage the development of infection by organisms not susceptible to the regimen being used. Superinfection in patients being treated for intra-abdominal infection can be caused by *Candida*; however, enterococci or opportunistic gram-negative bacilli such as *Pseudomonas* may be involved.

Treatment regimens for intra-abdominal infection can be judged as successful if the patient recovers from the infection without recurrent peritonitis or intra-abdominal abscess and without the need for additional antimicrobials. A regimen can be considered unsuccessful if a significant adverse drug reaction occurs, reoperation or percutaneous drainage is necessary, or patient improvement is delayed beyond 1 or 2 weeks. The costs of treatment can be significantly reduced if parenteral antimicrobials can be switched to oral agents for completion of therapy.[101]

ABBREVIATIONS

APACHE	acute physiology and chronic health evaluation
CAPD	chronic ambulatory peritoneal dialysis

SELF-ASSESSMENT QUESTIONS

1. A patient presents with an abscess in the abdomen, most likely associated with a perforated diverticulum in the colon. Which of the following would be the most appropriate initial antimicrobial regimen?
   A. Ceftriaxone plus metronidazole
   B. Clindamycin
   C. Ampicillin–sulbactam
   D. Gentamicin plus metronidazole
2. Which of the following is the best choice for complicated intra-abdominal infections due to extended-spectrum β-lactamase-producing Enterobacterales?
   A. Tigecycline
   B. Sulfamethoxazole/trimethoprim
   C. Polymyxin B or Colistin
   D. Meropenem
3. The appropriate duration of antimicrobial treatment for acute contamination of the abdomen without established infection is:
   A. 24 hours or less
   B. 10 days
   C. 3 days
   D. 4-7 days
4. Which of the following would be considered optimal therapy for community-acquired acute cholecystitis?
   A. Meropenem

   B. Ciprofloxacin

   C. Ceftriaxone

   D. Cefepime

5. Identify the correct statement:

   A. Mild-to-moderate community-acquired complicated intra-abdominal infections DO NOT require empiric coverage for *Enterococcus* spp.

   B. Empiric coverage for methicillin-resistant *Staphylococcus aureus* is routinely required for healthcare-associated complicated intra-abdominal infections.

   C. Empiric coverage for *Candida* spp. is routinely required for high-risk/severe community-acquired complicated intra-abdominal infections.

   D. Empiric coverage for *Candida* spp. is routinely required for mild-to-moderate community-acquired complicated intra-abdominal infections.

6. In patients with primary peritonitis, bacteria may enter the abdomen via all of the following routes, except:

   A. Through a cerebrospinal–peritoneal shunt

   B. Through the damage done to the GI tract by blunt trauma

   C. Through the bloodstream when there is no damage to the GI tract

   D. Through a peritoneal dialysis catheter

7. Which of the following statements is false?

   A. Antimicrobial regimens for secondary intra-abdominal infections should cover a broad spectrum of aerobic and anaerobic bacteria.

   B. Antimicrobial treatment of acute bacterial contamination after trauma to the GI tract is adequately treated with an antianaerobic cephalosporin.

   C. Most patients should not complete their antimicrobial regimen orally after an uncomplicated secondary intra-abdominal infection.

   D. Four to 7 days of antimicrobial treatment is typically adequate for intra-abdominal infections with adequate source control.

8. The polymorphonuclear (PMN) leukocyte count from ascitic fluid consistent with bacterial peritonitis is:

   A. >100 PMN/mm^3 (0.1 × 10^9/L)

   B. >250 PMN/mm^3 (0.25 × 10^9/L)

   C. >500 PMN/mm^3 (0.5 × 10^9/L)

   D. >1,000 PMN/mm^3 (1.0 × 10^9/L)

9. Which of the following requires the empiric coverage of anaerobes?

   A. Primary (spontaneous) bacterial peritonitis

   B. Community-acquired acute cholecystitis

   C. Mild-to-moderate community-acquired complicated intra-abdominal infection

   D. Peritoneal dialysis-associated peritonitis

10. Which of the following regimens is reliably active against both Enterobacterales such as *E. coli* AND anaerobes such as *Bacteroides fragilis*?

A. Levofloxacin

B. Ceftriaxone plus metronidazole

C. Cefepime plus clindamycin

D. Ampicillin/sulbactam

11. Identify the incorrect statement regarding complicated healthcare-associated intra-abdominal infections in adults.

A. Microbiologic results and the patient's history of infecting organisms should guide empiric antibiotic therapy.

B. Ampicillin–sulbactam is appropriate for the treatment of complicated healthcare-associated, complicated intra-abdominal infections.

C. Piperacillin–tazobactam is appropriate for the treatment of healthcare-associated complicated intra-abdominal infections.

D. Ertapenem is appropriate for the treatment of complicated healthcare-associated intra-abdominal infections.

12. Which of the following organisms should be routinely treated empirically in patients with high-risk/severe community-acquired complicated intra-abdominal infection?

A. Vancomycin-resistant *Enterococcus* spp.

B. Methicillin-resistant *Staphylococcus aureus*

C. *Pseudomonas aeruginosa*

D. *Acinetobacter baumannii*

13. The most reasonable initial intraperitoneal empiric antimicrobial therapy for a 46-year-old male patient with peritoneal dialysis-associated peritonitis and a history of immediate hypersensitivity reaction (reaction occurred within the last year) to penicillin is:

A. Cefazolin plus ceftazidime (LD 500 mg/L, MD 125 mg/L for each)

B. Cefepime (LD 500 mg/L, MD 125 mg/L)

C. Vancomycin (LD 1,000 mg/L, MD 25 mg/L) plus tobramycin (LD 8 mg/L, MD 4 mg/L)

D. Metronidazole (LD 250 mg/L, MD 50 mg/L)

14. A 23-year-old woman who is not severely ill and is otherwise in good health is determined to have a perforated appendix. Which of the following is the best antimicrobial regimen for this patient?

A. Cefazolin plus vancomycin

B. Ceftriaxone plus metronidazole

C. Aztreonam plus vancomycin

D. Cefazolin plus gentamicin

15. The most important component of treatment of a perforated appendix is:

A. Using the best antimicrobial regimen

B. Aggressive IV fluid therapy

C. A surgical procedure, including drainage and repair

D. Enteral nutrition supplementation

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Explanation: This patient presents with a community-acquired intra-abdominal infection and abscess. The most likely pathogens based on anatomical location, nature of infection are *Streptococcus*, anaerobes such as *Bacteroides*, and Enterobacterales. The only regimen that provides adequate empiric coverage for these is A. B is incorrect because it lacks both Enterobacterales and adequate *Bacteroides* coverage. C is incorrect due to increasing rates of resistance among Enterobacterales. An aminoglycoside is unnecessary for this patient and carries significant toxicity risk, so D is incorrect.

2. **D.** Explanation: The drug of choice for extended-spectrum β-lactamase-producing Enterobacterales is typically carbapenems (D is correct). Tigecycline may be active; however, it should be reserved for patients who have no other therapeutic options given the potential for increased risk of toxicity and mortality with tigecycline. The polymyxins should also be reserved for patients with multidrug-resistant pathogens where no other agents are active. Sulfamethoxazole/trimethoprim is unlikely to be active given ESBL-containing plasmids usually display additional resistant genotypes including to sulfamethoxazole/trimethoprim and fluoroquinolones.

3. **A.** Explanation: For acute stomach and proximal jejunum perforations, in the absence of acid-reducing therapy or malignancy and when source control is achieved within 24 hours, prophylactic anti-infective therapy directed at aerobic gram-positive cocci for 24 hours is adequate. Furthermore, bowel injuries attributable to penetrating, blunt, or iatrogenic trauma that are repaired within 12 hours and any other intraoperative contamination of the operative field by enteric contents should be treated with antibiotics for ≤24 hours.

4. **C.** Explanation: *Streptococcus* and Enterobacterales coverage is required for this indication, ceftriaxone provides good coverage for both. Cefepime and meropenem are incorrect because *Pseudomonas* coverage is not needed. Ciprofloxacin is not ideal given a significant risk of Enterobacterales resistance and poor *Streptococcus* coverage.

5. **A.** Explanation: Answer B is incorrect, MRSA is an unlikely cause of complicated intra-abdominal infections thus should be only used in healthcare-associated, complicated intra-abdominal infections where specific MRSA risk factors are present. C and D are incorrect because empiric coverage for *Candida* should not routinely be used for complicated intra-abdominal infections. However, if *Candida* is isolated in appropriate culture, typically it should be treated.

6. **B.** Explanation: Peritonitis resulting from damage done to the GI tract from blunt trauma would be classified as secondary peritonitis.

7. **C.** Explanation: Oral therapy is reasonable for patients with uncomplicated secondary intra-abdominal infection as long as the regiment is likely or confirmed to be active.

8. **B.** Explanation: Ascitic fluid with >250/mm^3 (0.25×10^9/L) PMN is suggestive of spontaneous bacterial peritonitis.

9. **C.** Explanation: Of the infections listed, only patients with complicated intra-abdominal infections require anaerobic coverage.

10. **B.** Explanation: Levofloxacin and ampicillin/sulbactam are less likely to be active empirically for Enterobacterales relative to ceftriaxone or cefepime. Levofloxacin also lacks significant *Bacteroides* coverage. Clindamycin does not have reliable *Bacteroides* coverage.

11. **B.** Explanation: Ampicillin/sulbactam lacks *Pseudomonas* coverage which is required in healthcare-associated complicated intra-abdominal infections. Ampicillin/sulbactam also has poor empiric activity for Enterobacterales.

12. **C.** Explanation: *Pseudomonas* should be routinely covered empirically in patients with high-risk/severe, community-acquired complicated intra-abdominal infection. VRE, MRSA, and *Acinetobacter* coverage is not routinely needed given the infrequency of those organisms in community-acquired disease.

13. **C.** Explanation: Initial empiric regimens for peritoneal dialysis-associated peritonitis should be active against both gram-positive (including *S. aureus*) and gram-negative pathogens including Enterobacterales and *Pseudomonas*. Cefepime monotherapy is reasonable empiric therapy; however,

the patient's immediate hypersensitivity reaction to penicillin precludes cefepime use. Response A is also incorrect for the same reason and furthermore using two cephalosporins at the same time is suboptimal. Metronidazole only covers anaerobes which are not likely to be causative of this syndrome. The only other option that has the required spectrum and is safe given the patient's allergy history is response C.

14. **B.** Explanation: Patients presenting from the community with perforated appendix where antibiotic therapy is used can receive the same treatment as those complicated intra-abdominal infection (in her case mild/moderate severity, answer B is correct).

15. **C.** Explanation: Uncomplicated appendicitis (defined as the absence of perforation, abscess, appendicolith, CT consistent with possible tumor, peritonitis, severe systemic illness) may be treated nonsurgically, with antibiotics alone. However, if perforated, drainage and repair is required to decrease morbidity (answer C is correct). Fluids, enteral nutrition, and even antibiotic therapy are less important relative to source control in patients with perforated appendicitis.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 139: Urinary Tract Infections

Julianna M. Fernandez; Elizabeth A. Coyle

KEY CONCEPTS

KEY CONCEPTS

①Urinary tract infections (UTIs) can be classified as uncomplicated and complicated. *Uncomplicated* refers to an infection in an otherwise healthy, premenopausal female who lacks structural or functional abnormalities of the urinary tract. Most often complicated infections are associated with a predisposing lesion of the urinary tract; however, the term may be used to refer to all other infections, except for those in the otherwise healthy, premenopausal adult female.

②Recurrent UTIs are considered either reinfections or relapses. Reinfection usually happens more than 2 weeks after the last UTI and is treated as a new uncomplicated UTI. Relapse usually happens within 2 weeks of the original infection and is a relapse of the original infection because of unsuccessful treatment of the original infection, a resistant organism, or anatomical abnormalities.

③The majority (75%-90%) of uncomplicated UTIs are caused by *Escherichia coli* and the remainder are caused primarily by *Staphylococcus saprophyticus*, Proteus spp., and Klebsiella spp. Complicated infections may be associated with other gram-negative organisms and *Enterococcus faecalis.*

④Symptoms of lower UTIs include dysuria, urgency, frequency, nocturia, and suprapubic heaviness, whereas upper UTIs involve more systemic symptoms such as fever, nausea, vomiting, and flank pain.

⑤Significant bacteriuria has been defined as bacterial counts of greater than 10^5 organisms (colony-forming unit [CFU])/mL (10^8 CFU/L) of a midstream clean catch urine. However, this is too general and significant bacteriuria in patients with symptoms of UTI may be defined as greater than 10^2 organisms (CFU)/mL (10^5 CFU/L).

⑥The goals of treatment of UTIs are to eradicate the invading organism(s), prevent or treat systemic consequences of infections, prevent the recurrence of infection, and prevent antimicrobial resistance.

⑦Uncomplicated UTIs can be managed most effectively with short-course therapy (3 days) with either trimethoprim–sulfamethoxazole, one dose of fosfomycin, or 5 days of nitrofurantoin. Fluoroquinolones should be reserved for suspected pyelonephritis or complicated infections.

⑧When choosing appropriate antibiotic therapy, practitioners need to be cognizant of antibiotic resistance patterns, particularly to *E. coli.* Trimethoprim–sulfamethoxazole has diminished activity against *E. coli* in some areas of the country, with reported resistance in some areas greater than 20%.

⑨Acute bacterial prostatitis can be managed with many agents that have activity against the causative organism. Chronic prostatitis requires prolonged therapy with an agent that penetrates the prostatic tissue and secretions. Therapy with fluoroquinolone or trimethoprim–sulfamethoxazole is preferred for up to 6 weeks.

BEYOND THE BOOK

BEYOND THE BOOK

EY, a 28-year-old pregnant female presents to her OB clinic for a routine week 18 appointment. Her past medical history is unremarkable except for seasonal allergies. In the clinic, she is hemodynamically stable with a BP 130/72 mmHg, HR 78 BPM, RR 16, and temperature 97.5°F (36.4°C). Her home medications include a daily maternal multivitamin and diphenhydramine PRN. The patient denies any dysuria, urinary frequency, costovertebral angle tenderness, or suprapubic pain.

1. Should this patient be screened for urinary tract infection?
2. Which of the following clinical or laboratory features places this patient at an increased risk of a complicated UTI?
    a. Age
    b. Pyuria
    c. Pregnancy
    d. Positive leukocyte esterase
3. Which of the following would be most appropriate in managing EY's bacteriuria?
    a. Ciprofloxacin 500 mg orally twice daily for 3 days
    b. Antibiotics not indicated now
    c. Trimethoprim/sulfamethoxazole 800/160mg twice daily for 10 days
    d. Nitrofurantoin 100 mg orally twice daily for 7 days.
4. Three days later, EY calls the clinic because she has a low-grade fever (99.5°F [37.5°C]) and is complaining of having pyuria, frequent urination, and intermittent back pain. She has been busy the past few days and has not had a chance to pick up her prescription. The culture from the urinalysis from 3 days ago has grown out E. coli that is sensitive to ciprofloxacin, nitrofurantoin, fosfomycin, and trimethoprim/sulfamethoxazole. Which of the following is the best recommendation for EY now?
    a. Trimethoprim/sulfamethoxazole 800/160mg twice daily for 14 days
    b. Start the prescription from 3 days ago
    c. Levofloxacin 250 mg orally daily for 7 days
    d. Piperacillin/tazobactam 3.375 g IV every 6 hours for 7 days

INTRODUCTION

Infections of the urinary tract represent a wide variety of syndromes, including urethritis, cystitis, prostatitis, and pyelonephritis. Urinary tract infections (UTIs) are the most commonly occurring bacterial infections and one of the most common reasons for antibiotic exposure, especially in females of childbearing age.[1–3] Approximately 60% of females will develop a UTI during their lifetime with about one-fourth having a recurrence within a year.[2] Infections in males occur much less frequently until the age of 65 years at which point the incidence rates in males and females are similar.

UTI is defined as the presence of microorganisms in the urinary tract that cannot be accounted for by contamination. The organisms present have the potential to invade the tissues of the urinary tract and adjacent structures. Infection may be limited to the growth of bacteria in the urine, which frequently may not produce symptoms. UTI can present as several syndromes associated with an inflammatory response to microbial invasion and can range from asymptomatic bacteriuria (ASB) to pyelonephritis with bacteremia or sepsis.

UTIs are classified as lower and upper UTIs. Typically, they have been described by anatomic site of involvement. Lower tract infections correspond to cystitis (bladder), and pyelonephritis (an infection involving the kidneys) represents upper tract infection.

① Also, UTIs are designated as uncomplicated or complicated. Uncomplicated infections occur in individuals who lack structural or functional abnormalities of the urinary tract which interfere with the normal flow of urine or voiding mechanism. These infections occur in premenopausal females of childbearing age (15-45 years) who are otherwise normal, healthy individuals. Infections in males generally are not classified as uncomplicated because these infections are rare and most often represent a structural or neurologic abnormality.

Complicated UTIs are usually the result of a predisposing lesion of the urinary tract, such as a congenital abnormality or distortion of the urinary tract, a stone, indwelling catheter, prostatic hypertrophy, obstruction, or neurologic deficit that interferes with the normal flow of urine and urinary tract defenses. Complicated infections occur in both genders and frequently involve the upper and lower urinary tract.

② Recurrent UTIs in healthy nonpregnant females—two or more UTIs occurring within 6 months or three or more UTIs within 1 year—are a common problem. They are characterized by multiple symptomatic infections with asymptomatic periods occurring between each episode and may be either reinfections or relapses. Reinfections are caused by a different organism than originally isolated and account for the majority of recurrent UTIs. Relapses are the development of repeated infections with the same initial organism and usually indicate a persistent infectious source.[2]

ASB is a common finding, particularly among those 65 years of age and older when there is significant bacteriuria (more than 10^5 bacteria/mL [10^8/L] of urine) in the absence of signs or symptoms. Symptomatic abacteriuria or acute urethral syndrome consists of symptoms of frequency and dysuria in the absence of significant bacteriuria. This syndrome is commonly associated with *Chlamydia* infections.

Significant abacteriuria is a term used to distinguish the presence of microorganisms that represent true infection versus contamination of the urine as it passes through the distal urethra prior to collection. Historically, bacterial counts equal to or greater than 100,000 organisms/mL (10^8/L) of urine in a "clean-catch" specimen were judged to indicate true infection.[4–6] Counts less than 100,000 organisms/mL (10^8/L) of urine, however, may represent true infection in certain situations, for example, with concurrent antibacterial drug administration, rapid urine flow, low urinary pH, or upper tract obstruction.[6] Table 139-1 lists the clinical definitions of significant bacteriuria, which are dependent on the clinical setting and the method of specimen collection.[6] These criteria allow for more appropriate specificity and sensitivity in documenting infection under differing clinical circumstances.

TABLE 139-1

Diagnostic Criteria for Significant Bacteriuria

- $\geq 10^2$ CFU coliforms/mL (10^5 CFU/L) or $\geq 10^5$ CFU noncoliforms/mL (10^8 CFU/L) in a symptomatic female
- $\geq 10^4$ CFU bacteria/mL (10^7 CFU/L) in a symptomatic male
- $\geq 10^5$ CFU bacteria/mL (10^8 CFU/L) in asymptomatic individuals on two consecutive specimens
- Any growth of bacteria on suprapubic catheterization in a symptomatic patient
- $\geq 10^{2\text{-}5}$ CFU bacteria/mL ($10^{5\text{-}8}$ CFU/L) in a catheterized patient

CFU, colony-forming unit.

EPIDEMIOLOGY

The prevalence of UTIs varies with age and gender. In newborns and infants up to 6 months of age, the prevalence of abacteriuria is approximately 1% and is more common in boys. Most of these infections are associated with structural or functional abnormalities of the urinary tract and also have been correlated with noncircumcision.[7] Between the ages of 1 and 6 years, UTIs occur more frequently in females. The prevalence of abacteriuria in females and males of this age group is 3% to 7% and 1% to 2%, respectively.[7,8] Infections occurring in preschool boys usually are associated with congenital abnormalities of the urinary tract. These infections are difficult to recognize because of the age of the patient, but they often are symptomatic. In addition, the majority of renal damage associated with UTI develops at this age.[7,8]

Through grade school and before puberty, the prevalence of UTI is approximately 1%, with 5% of females reported to have significant bacteriuria prior to leaving high school. This percentage increases dramatically to 1% to 4% after puberty in nonpregnant females primarily as a result of sexual activity. Approximately one in five women will suffer a symptomatic UTI at some point in their lives. Many females have recurrent infections with a significant proportion having a history of childhood infections. In contrast, the prevalence of bacteriuria in adult males is low (less than 0.1%).[9]

In the older adults, the ratio of bacteriuria in women and men is dramatically altered and is approximately equal in persons older than 65 years. The overall incidence of UTI increases substantially in this population with the majority of infections being asymptomatic. The rate of infection increases further for older adults who are residing in nursing homes, particularly those who are hospitalized frequently. A variety of factors increase the risk of infection including structural and anatomical changes such as benign prostatic hypertrophy in males and prolosapse in women resulting in either urinary retention or incontinence, respectively. Patients suffering from fecal incontinence as a complication of advanced dementia or neuromuscular disease including strokes are also at increased risk. Urinary instrumentation (catheterization) along with some medications such as the sodium-glucose co-transporter inhibitors also creates an environment that is more supportive of UTIs.[10]

ETIOLOGY

③The bacteria causing UTIs usually originate from bowel flora of the host. Although virtually every organism is associated with UTIs, certain organisms predominate as a result of specific virulence factors. The most common cause of uncomplicated UTIs is *Escherichia coli*, which accounts for 80% to 90% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus*, *Klebsiella pneumoniae*, *Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp.[11] Because *S. epidermidis* is frequently isolated from the urinary tract, it should be considered initially a contaminant. Repeat cultures should be performed to help confirm the organism as a real pathogen.

Organisms isolated from individuals with complicated infections are more varied and generally are more resistant than those found in uncomplicated infections. *E. coli* is a frequently isolated pathogen, but it accounts for less than 50% of infections. Other frequently isolated organisms include *Proteus* spp., *K. pneumoniae*, *Enterobacter* spp., *P. aeruginosa*, staphylococci, and enterococci. Enterococci represent the second most frequently isolated organisms in hospitalized patients.[11–13] In part, this finding may be related to the extensive use of third-generation cephalosporin antibiotics, which are not active against the enterococci. Vancomycin-resistant *E. faecalis* and *E. faecium* (vancomycin-resistant enterococci) have become more widespread, especially in patients with long-term hospitalizations or underlying malignancies. Vancomycin-resistant enterococci are major therapeutic and infection control issues because these organisms are susceptible to few antimicrobials.[12,13] *S. aureus* infections may arise from the urinary tract, but they are more commonly a result of bacteremia producing metastatic abscesses in the kidney. *Candida* spp. are common causes of UTI in the critically ill and chronically catheterized patient. Most UTIs are caused by a single organism; however, in patients with stones, indwelling urinary catheters, or chronic renal abscesses, multiple organisms may be isolated. Depending on the clinical situation, the recovery of multiple organisms may represent contamination and a repeat evaluation should be done.

PATHOPHYSIOLOGY

Route of Infection

Organisms typically gain entry into the urinary tract via three routes: the ascending, hematogenous (descending), and lymphatic pathways. The female urethra usually is colonized by bacteria believed to originate from the fecal flora. The short length of the female urethra and its proximity to the perirectal area make colonization of the urethra likely. Other factors that promote urethral colonization include the use of spermicides and diaphragms as methods of contraception.[2,3] Although there is evidence in females that bladder infections follow colonization of the urethra, the mode of ascent of the microorganisms is incompletely understood. Massage of the female urethra and sexual intercourse allow bacteria to reach the bladder.[14] Once bacteria have reached the bladder, the organisms quickly multiply and can ascend the ureters to the kidneys. This sequence of events is more likely to occur if vesicoureteral reflux (reflux of urine into the ureters and kidneys while voiding) is present. UTIs are more common in females than in males because the anatomic differences in location and length of the urethra tend to support the ascending route of infections as the primary acquisition route.

Infection of the kidney by hematogenous spread of microorganisms usually occurs as the result of dissemination of organisms from a distant primary infection in the body. Infections via the descending route are uncommon and involve a relatively small number of invasive pathogens. Bacteremia caused by *S. aureus* may produce renal abscesses. Additional organisms include *Candida* spp., *Mycobacterium tuberculosis*, *Salmonella* spp., and enterococci. Of particular interest, it is difficult to produce experimental pyelonephritis by IV administration of common gram-negative organisms such as *E. coli* and *P. aeruginosa*. Overall, less than 5% of documented UTIs results from hematogenous spread of microorganisms.

There appears to be little evidence supporting a significant role for renal lymphatics in the pathogenesis of UTIs. There are lymphatic communications between the bowel and kidney, as well as between the bladder and kidney. There is no evidence, however, that microorganisms are transferred to the kidney via this route. After bacteria reach the urinary tract, three factors determine the development of infection: the size of the inoculum, the virulence of the microorganism, and the competency of the natural host defense mechanisms. Most UTIs reflect a failure in host defense mechanisms.

Host Defense Mechanisms

The normal urinary tract generally is resistant to invasion by bacteria and is efficient in rapidly eliminating microorganisms that reach the bladder. The urine under normal circumstances is capable of inhibiting and killing microorganisms. The factors thought to be responsible include a low pH, extremes in osmolality, high urea concentration, and high organic acid concentration. Bacterial growth is further inhibited in males by the addition of prostatic secretions.[14,15]

The introduction of bacteria into the bladder stimulates micturition with increased diuresis and efficient emptying of the bladder. These factors are critical in preventing the initiation and maintenance of bladder infections. Patients who are unable to void urine completely are at greater risk of developing UTIs and frequently have recurrent infections. Also, patients with even small residual amounts of urine in their bladder respond less favorably to treatment than patients who are able to empty their bladders completely.[16]

An important virulence factor of bacteria is their ability to adhere to urinary epithelial cells resulting in colonization of the urinary tract, bladder infections, and pyelonephritis. Various factors that act as anti-adherence mechanisms are present in the bladder preventing bacterial colonization and infection. The epithelial cells of the bladder are coated with a urinary mucus or slime called *glycosaminoglycan*. This thin layer of surface mucopolysaccharide is hydrophilic and strongly negatively charged. When bound to the uroepithelium, it attracts water molecules and forms a layer between the bladder and urine. The anti-adherence characteristics of the glycosaminoglycan layer are nonspecific and when the layer is removed by dilute acid solutions, rapid bacterial adherence results.[17]

In addition, the Tamm–Horsfall protein is a glycoprotein produced by the ascending limb of Henle and distal tubule that is secreted into the urine and contains mannose residues. These mannose residues bind *E. coli* that contain small surface-projecting organelle on their surfaces called *pili* or *fimbriae*. Type 1 fimbriae are mannose-sensitive, and this interaction prevents the bacteria from binding to similar receptors present on the mucosal surface of the bladder. Other factors that possibly prevent adherence of bacteria include immunoglobulins (Ig) G and A, which are synthesized systemically and in the kidney with upper tract infections. The role of Igs in preventing bladder infection is less clear. Patients with reduced urinary levels of secretory IgA are, however, at increased risk of infections of the urinary tract.

After bacteria have invaded the bladder mucosa, an inflammatory response is stimulated with the mobilization of polymorphonuclear leukocytes (PMNs) and resulting phagocytosis. PMNs are primarily responsible for limiting the tissue invasion and controlling the spread of infection in the bladder and kidney. They do not play a role in preventing bladder colonization or infections and actually contribute to renal tissue damage.

Other host factors that may play a role in the prevention of UTIs are the presence of *Lactobacillus* in the vaginal flora and circulating estrogen levels. In premenopausal women, circulating estrogen supports the vaginal tract growth of lactobacilli, which produce lactic acid to help maintain a low vaginal pH, thereby preventing *E. coli* vaginal colonization.[18] Topical estrogens are used for the prevention of UTI in postmenopausal women who have more than three recurrent UTI episodes per year and are not on oral estrogens.[19]

Bacterial Virulence Factors

Pathogenic organisms have differing degrees of pathogenicity (virulence), which play a role in the development and severity of infection. Bacteria that adhere to the epithelium of the urinary tract are associated with colonization and infection. The mechanism of adhesion of gram-negative bacteria, particularly *E. coli*, is related to bacterial fimbriae that are rigid, hair-like appendages of the cell wall.[9] These fimbriae adhere to specific glycolipid components on epithelial cells. The most common type of fimbriae is type 1, which binds to mannose residues present in glycoproteins. Glycosaminoglycan and Tamm–Horsfall protein are rich in mannose residues that readily trap those organisms that contain type 1 fimbriae, which are then washed out of the bladder.[20] Other fimbriae are mannose-resistant and are associated more frequently with pyelonephritis, such as P fimbriae, which bind avidly to specific glycolipid receptors on uroepithelial cells. These bacteria are resistant to washout or removal by glycosaminoglycan and are able to multiply and invade tissue, especially the kidney. In addition, PMNs, as well as secretory IgA antibodies, contain receptors for type 1 fimbriae, which facilitate phagocytosis, but are lacking receptors for P fimbriae.

Other virulence factors include the production of hemolysin and aerobactin.[21] Hemolysin is a cytotoxic protein produced by bacteria that lyses a wide range of cells, including erythrocytes, PMNs, and monocytes. *E. coli* and other gram-negative bacteria require iron for aerobic metabolism and multiplication. Aerobactin facilitates the binding and uptake of iron by *E. coli*; however, the significance of this property in the pathogenesis of UTIs remains unknown.[22]

PREDISPOSING FACTORS TO INFECTION

The normal urinary tract typically is resistant to infection and colonization by pathogenic bacteria. In patients with underlying structural abnormalities of the urinary tract, the typical host defenses previously discussed usually are lacking or compromised. There are several known abnormalities of the urinary tract system that interfere with its natural defense mechanisms, the most important of which is obstruction. Obstruction can inhibit the normal flow of urine disrupting the natural flushing and voiding effect in removing bacteria from the bladder and resulting in incomplete emptying. Common conditions that result in residual urine volumes include prostatic hypertrophy, urethral strictures, calculi, tumors, bladder diverticula, and drugs such as anticholinergic agents. Additional causes of incomplete bladder emptying include neurologic malfunctions associated with stroke, diabetes, spinal cord injuries, tabes dorsalis, and other neuropathies. Vesicoureteral reflux represents a condition in which urine is forced up the ureters to the kidneys. Urinary reflux is associated not only with an increased incidence of UTIs and pyelonephritis but also with renal damage.[8,16] Reflux may be the result of a congenital abnormality or, more commonly, bladder overdistension from obstruction. Other risk factors include urinary catheterization, mechanical instrumentation, pregnancy, and the use of spermicides and diaphragms.

CLINICAL PRESENTATION

④ The presenting signs and symptoms of UTIs in adults are recognized easily. Females frequently will report gross hematuria. Systemic symptoms, including fever, typically are absent in this setting. Unfortunately, large numbers of persons with significant bacteriuria are asymptomatic. These individuals may be normal, healthy persons, older adults, children, pregnant persons, and persons with indwelling catheters. Attempts at differentiating upper tract from lower tract infections on the basis of symptoms alone are not reliable.

CLINICAL PRESENTATION: Urinary Tract Infections in Adults

Signs and Symptoms

- Lower UTI: Dysuria, urgency, frequency, nocturia, and suprapubic heaviness
- Gross hematuria
- Upper UTI: Flank pain, fever, nausea, vomiting, and malaise

Physical Examination

- Upper UTI: Costovertebral tenderness

Laboratory Tests

- Bacteriuria
- Pyuria (WBC count more than 10/mm^3 [10 × 10^6/L])
- Nitrite-positive urine (with nitrite reducers)
- Leukocyte esterase-positive urine
- Antibody-coated bacteria (upper UTI)

Older adults frequently do not experience specific urinary symptoms, but they will present with altered mental status, change in eating habits, or gastrointestinal (GI) symptoms. In addition, patients with indwelling catheters or neurologic disorders commonly will not have lower tract symptoms. Instead, they may present with flank pain and fever. Many of the aforementioned patients, however, frequently will develop upper tract infections with bacteremia and no or minimal urinary tract symptoms.

Symptoms alone are unreliable for the diagnosis of bacterial UTIs. The key to the diagnosis of UTI is the ability to demonstrate significant numbers of microorganisms in an appropriate urine specimen to distinguish contamination from infection. The type and extent of laboratory examination required depends on the clinical situation.

Urine Collection

Examination of the urine is the cornerstone of laboratory evaluation for UTIs. There are three acceptable methods of urine collection. The first is the *midstream clean-catch method*. After cleaning the urethral opening area in both men and women, 20 to 30 mL of urine is voided and discarded. The next part of the urine flow is collected and should be processed immediately (refrigerated as soon as possible). Specimens that are allowed to sit at room temperature for several hours may result in falsely elevated bacterial counts. The midstream clean-catch is the preferred method for the routine collection of urine for culture. When a routine urine specimen cannot be collected or contamination occurs, alternative collection techniques must be used.

The two acceptable alternative methods include catheterization and suprapubic bladder aspiration. Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with the aseptic technique, the method yields reliable results. However, the introduction of bacteria into the bladder may result and the procedure is associated with infection in 1% to 2% of patients. Suprapubic bladder aspiration involves inserting a needle directly into the bladder and aspirating the urine. This procedure bypasses the contaminating organisms present in the urethra and any bacteria found using this technique generally are considered to represent significant bacteriuria.[23–26] Suprapubic aspiration is a safe and painless procedure that is most useful in newborns, infants, paraplegics, seriously ill patients, and others in whom infection is suspected and routine procedures have provided confusing or equivocal results.

Bacterial Count

⑤The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Microscopic examination of a urine sample is an easy-to-perform and reliable method for the presumptive diagnosis of bacteriuria. The examination may be performed by preparing a Gram stain of unspun or centrifuged urine. The presence of at least one organism per oil-immersion field in a properly collected uncentrifuged specimen correlates well with more than 100,000 CFU/mL (10^5 CFU/mL or 10^8 CFU/L) of urine. For detecting smaller numbers of organisms, a centrifuged specimen is more sensitive. Such examinations detect more than 10^5 bacteria (CFU)/mL (10^8 CFU/L) with a sensitivity of greater than 90% and a specificity of greater than 70%.[23,24] A quantitative count of greater than or equal to 10^5 CFU/mL (10^8 CFU/L) is considered indicative of a UTI; however, up to 50% of women will present with clinical symptoms of a UTI with lower counts (10^3 CFU/mL) (10^6 CFU/L).[4]

Pyuria, Hematuria, and Proteinuria

Microscopic examination of the urine for leukocytes is used to determine the presence of pyuria. The presence of pyuria in a symptomatic patient correlates with significant bacteriuria.[25] Pyuria is defined as a white blood cell (WBC) count of greater than 10 WBC/mm^3 (10×10^6/L) of urine. A count of 5 to 10 WBC/mm^3 (5×10^6 to 10×10^6/L) is accepted as the upper limit of normal. It should be emphasized that pyuria is nonspecific and signifies only the presence of inflammation and not necessarily infection. Thus, patients with pyuria may or may not have infection. Sterile pyuria has long been associated with urinary tuberculosis, as well as chlamydial and fungal urinary infections. Hematuria, microscopic or gross, is frequently present in patients with UTI, but is nonspecific. Hematuria may indicate the presence of other disorders, such as renal calculi, tumors, or glomerulonephritis. Proteinuria is found commonly in the presence of infection.

Chemistry

Several biochemical tests have been developed for screening urine for the presence of bacteria. A common dipstick test detects the presence of nitrite in the urine, which is formed by bacteria that reduce nitrate normally present in the urine. False-positive tests are uncommon. False-negative tests are more common and are frequently caused by the presence of gram-positive organisms or *P. aeruginosa* that do not reduce nitrate.[26] Other causes of false tests include low urinary pH, frequent voiding, and dilute urine.

The leukocyte esterase dipstick test is a rapid screening test for detecting the presence of pyuria. Leukocytes esterase is found in primary neutrophil granules and indicates the presence of WBCs. The leukocyte esterase test is a sensitive and highly specific test for detecting more than 10 WBC/mm^3 (10×10^6/L) of urine. When the leukocyte esterase test is used with the nitrite test, the reported positive predictive value and specificity are 79% and 82%, respectively, for the detection of bacteriuria.[27,28] These tests can be useful in the outpatient evaluation of uncomplicated UTIs. However, urine culture is still the "gold standard" test in determining the presence of UTIs.

Culture

The most reliable method of diagnosing UTI is by quantitative urine culture. Urine in the bladder is normally sterile making it possible to differentiate contamination of the urine from infection by quantifying the number of bacteria present in a urine sample. This criterion is based on a properly collected midstream clean-catch urine specimen. Patients with infection usually have greater than 10^5 bacteria/mL (10^8/L) of urine. However, as many as one-third of females with symptomatic infection have less than 10^5 bacteria/mL (10^8/L). Also, a significant portion of patients with UTIs, either symptomatic or asymptomatic, have less than 10^5 bacteria/mL (10^8/L) of urine.

Several laboratory methods are used to quantify bacteria present in the urine. The most accurate method is the pour-plate technique. This method is unsuitable for a high-volume laboratory because it is expensive and time-consuming. The streak-plate method is an alternative that involves using a calibrated-loop technique to streak a fixed amount of urine on an agar plate. This method is used most commonly in diagnostic laboratories because it is simple to perform and less costly.

After identification and quantification are complete, the next step is to determine the susceptibility of the organism. There are several methods by which bacterial susceptibility testing may be performed. Knowledge of bacterial susceptibility and achievable urine concentration of the antibiotics puts the clinician in a better position to select an appropriate agent for treatment.

Infection Site

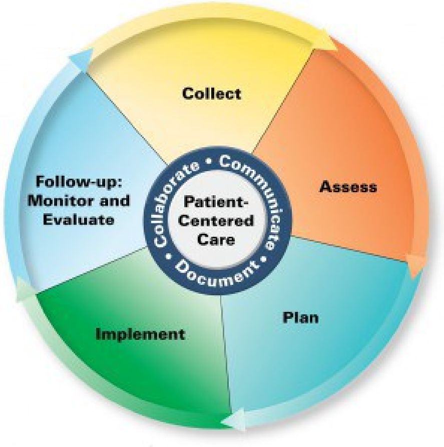
History and physical examination are of little value in predicting the site of infection. The most direct method to determine the location of infection within the urinary system and differentiate upper tract from lower tract involvement is a ureteral catheterization procedure as described by Stamey and colleagues.[29] The method involves the passage of a catheter into the bladder and then into each ureter, where quantitative cultures are obtained. Although this method provides direct quantitative evidence for UTI, it is invasive, technically difficult, and expensive. The Fairley bladder washout technique is a modification of the Stamey procedure that involves Foley catheterization only.[30] After the catheter is passed into the bladder, bladder samples are obtained, and the bladder is washed out with culture samples taken at 10, 20, and 30 minutes. The procedure shows that up to 50% of patients have renal involvement, regardless of signs and symptoms. Other investigators found 10% to 20% of tests to be equivocal.[30]

Noninvasive methods of localization may be more acceptable for routine use; however, they have limited clinical value. Patients with pyelonephritis can have abnormalities in urinary concentrating ability. The use of concentrating ability for localization of UTIs, however, is associated with high false-positive and false-negative responses and is not useful clinically.[26] The antibody-coated bacteria test is an immunofluorescent method that detects bacteria coated with Ig in freshly voided urine indicating upper UTI. The sensitivity and specificity of this test to localize the site of infection are reported to average 88% and 76%, respectively.[31] Because of the high incidence of false-positive and false-negative results, antibody-coated bacteria testing is not used routinely in the management of UTIs.

Virtually all patients with uncomplicated lower tract infections can be cured with a short course of antibiotic therapy and this assumption sometimes can be used to distinguish between patients with lower and upper tract infections. Patients who do not respond or who relapse may do so because of upper tract involvement. It is rarely necessary to localize the site of infection to direct the clinical management of such patients.

PATIENT CARE PROCESS

Patient Care Process for Urinary Tract Infection



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnant, immunocompetent)
- Patient symptoms (see Clinical Presentation box)
- Patient medical history (including history of past UTIs)
- Social history (eg, sexually active) and dietary habits
- Current medications including nonprescription and/or herbal products, dietary supplements
- Objective data

- Vital signs: blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2 saturation, temperature
- Labs including white blood cell count (WBC), serum creatinine (SCr)
- Urinalysis (eg, nitrite or leukocyte esterase +) +/− culture and sensitivity data
- Urine dipstick test
- Physical exam (eg, abdominal tenderness, costovertebral tenderness)

Assess

- Hemodynamic stability (eg, systolic BP <90 mm Hg >110 bpm)
- Mental status
- Urinary catheter present

Plan

- Drug therapy regimen including drug name, dose, route, frequency, and duration (see Tables 134-2, 134-3, and 134-4)
- Monitoring parameters including efficacy (eg, afebrile, WBC, urinalysis, resolution of symptoms), decrease in urinary discomfort and safety (eg, signs and symptoms of antibiotic hypersensitivity, SCr, WBC, hemodynamics)
- Patient education (eg, purpose of treatment, personal hygiene, drug-specific information, medication administration instructions, when to follow-up if no improvement observed; see Table 139-3)
- Self-monitoring for resolution of symptoms (eg, urinary discomfort, flank pain, fever, mental status changes)
- Referrals to other providers when appropriate (eg, urologist)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up if necessary

Follow-up: Monitor and Evaluate

- Resolution of urinary symptoms (eg, burning, discomfort during urination, flank pain, tenderness)
- Normalization of labs (eg, WBC, SCr)
- Urinalysis presence of adverse effects (eg, rash, diarrhea)
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate if patient does not respond adequately to treatment

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcomes

⑥ The goals of UTI treatments are (a) to eradicate the invading organism(s), (b) to prevent or to treat systemic consequences of infection, (c) to prevent the recurrence of infection, and (d) to decrease the potential for collateral damage with too broad of antimicrobial therapy.

Management

The management of a patient with a UTI includes initial evaluation, selection of an antibacterial agent, and duration of therapy and follow-up evaluation. The initial selection of an antimicrobial agent for the treatment of UTI is based primarily on the severity of the presenting signs and symptoms, the site of infection and whether the infection is determined to be uncomplicated or complicated. Other considerations include antibiotic susceptibility, side-effect potential, cost, current antimicrobial exposure, and the comparative inconvenience of different therapies.[1]

Various pharmacologic factors may affect the action of antibacterial agents. Certainly, the ability of the agent to achieve appropriate concentrations in the urine is of utmost importance. Factors that affect the rate and extent of excretion through the kidney include the patient’s glomerular filtration rate and whether or not the agent is actively secreted. Filtration depends on the molecular size and degree of protein binding of the agent. Agents such as sulfonamides, tetracyclines, and aminoglycosides enter the urine via filtration. As the glomerular filtration rate is reduced, the amount of drug that enters the urine is reduced. Most β-lactam agents and quinolones are filtered and are actively secreted into the urine. For this reason, most of these agents achieve high urinary concentrations despite unfavorable protein-binding characteristics or the presence of renal dysfunction.

The ability to eradicate bacteria from the urine is related directly to the sensitivity of the microorganism and the achievable concentrations of the antimicrobial agent in the urine. Unfortunately, most susceptibility testing is directed at achievable concentrations in the blood. There is a poor correlation between achievable blood concentrations of antimicrobial agents and the eradication of bacteria from the urine.[32] In the treatment of lower tract infections, plasma concentrations of antibacterial agents may not be important, but achieving appropriate plasma concentrations appears critical in patients with bacteremia and renal abscesses.

Nonspecific therapies have been advocated in the treatment and prevention of UTIs. Fluid hydration has been used to produce rapid dilution of bacteria and removal of infected urine by increased voiding. A critical factor appears to be the amount of residual volume remaining after voiding. As little as 10 mL of residual urine can alter the eradication of infection significantly.[16] Paradoxically, increased diuresis also may promote susceptibility to infection by diluting the normal antibacterial properties of the urine. Often in clinical practice, the concentrations of antimicrobial agents in the urine are so high that dilution has little effect on efficacy.

The antibacterial activity of the urine is related to the low pH, which is the result of high concentrations of various organic acids. Large volumes of cranberry juice increase the antibacterial activity of the urine and prevent the development of UTIs.[3,33] Apparently, the fructose and other unknown substances (condensed tannins, proanthocyanidin) in cranberry juice may act to interfere with adherence mechanisms of some pathogens, thereby preventing infection or reinfection. Acidification of the urine by cranberry juice does not appear to play a significant role. Although there are a number of favorable studies, the benefit of ingested cranberry juice appears to be minimal and larger studies involving oral tablets or capsules need to be done to prove effectivness.[35–38] Females with repeated UTIs who receive the recommended 36 mg/d of proanthocyanidins (found in cranberry products) may gain some benefit but studies remain largely inconclusive.[36–40] The use of other agents (ascorbic acid) to acidify the urine to try to hinder bacterial growth does not achieve significant enough acidification. Consequently, attempts to acidify urine with systemic agents are not recommended. Lactobacillus potentially helps keep the vaginal pH in the normal range (pH 4-4.5); therefore, regulating genitourinary bacteria aiding in the prevention of UTIs.[41] In addition, *Lactobacillus* probiotics may aid in the prevention of female UTIs by decreasing the vaginal pH, thereby decreasing *E. coli* colonization.[19,33,34] In postmenopausal women, estrogen replacement may be of help in the prevention of recurrent UTIs. After 1 month of topical estrogen replacement, vaginal *Lactobacillus* as well as vaginal pH and *E. coli* colonization decrease.[18,33]

Phenazopyridine hydrochloride is nonprescription urinary anesthetic/analgesic that can be used for symptom relief in UTIs. It is frequently used by patients as self-medication to alleviate the dysuria associated with UTIs. The use of phenazopyridine in the treatment of UTIs is controversial. It has no antimicrobial properties and has a number of adverse effects such as red-orange discoloration of body fluids, rash, anaphylaxis, and rare effects such as hemolytic anemia, methemoglobinemia, and acute renal failure. In addition, its use can mask the symptoms of an untreated or inappropriately treated UTI. Unfortunately, there are not any guidelines for its role in the treatment of UTIs; however, experts agree that if phenazopyridine is used, only use the recommended dose (maximum 200 mg three times a day) and limited to 1 to 2 days for symptomatic relief of the dysuria with UTIs.[41,42] In addition, it should be used with the combination of appropriate antibiotic therapy.

Pharmacologic Therapy

Ideally, the antimicrobial agent chosen should be well tolerated, well absorbed, achieve high urinary concentrations, and have a spectrum of activity limited to the known or suspected pathogen(s). Table 139-2 lists the most common agents used in the treatment of UTIs along with comments concerning their general use. Table 139-3 presents an overview of various therapeutic options for outpatient therapy of UTI. Table 139-4 describes empirical treatment regimens for selected clinical situations.

TABLE 139-2

Commonly Used Antimicrobial Agents in the Treatment of UTIs

Drug	Adverse Drug Reactions	Monitoring Parameters	Comments
Oral Therapy			
Trimethoprim–sulfamethoxazole	Rash, Stevens–Johnson Syndrome, renal failure, photosensitivity, hematologic (neutropenia, anemia, etc.)	Serum creatinine, BUN, electrolytes, signs of rash, and CBC	This combination is highly effective against most aerobic enteric bacteria except *P. aeruginosa*. High urinary tract tissue concentrations and urine concentrations are achieved, which may be important in complicated infection treatment. Also effective as prophylaxis for recurrent infections
Nitrofurantoin	GI intolerance, neuropathies, and pulmonary reactions	Baseline serum creatinine and BUN	This agent is effective as both a therapeutic and prophylactic agent in patients with recurrent UTIs. Main advantage is the lack of resistance even after long courses of therapy
Fosfomycin trometamol	Diarrhea, headache, and angioedema	No routine tests recommended	Single-dose therapy for uncomplicated infections, low levels of resistance, use with caution in patients with hepatic dysfunction
Fluoroquinolones			
Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms, dizziness, confusion, and tendonitis (black box warning)	CBC, baseline serum creatinine, and BUN	The fluoroquinolones have a greater spectrum of activity, including *P. aeruginosa*. These agents are effective for pyelonephritis and prostatitis. Avoid in pregnancy and children. Moxifloxacin should not be used owing to inadequate urinary concentrations
Amoxicillin–clavulanate	Hypersensitivity (rash, anaphylaxis), diarrhea,	CBC, signs of rash, or hypersensitivity	Due to increasing *E. coli* resistance, amoxicillin–clavulanate is the preferred penicillin for uncomplicated cystitis

	superinfections, and seizures		
Cephalosporins Cefaclor Cefpodoxime-proxetil	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	There are no major advantages of these agents over other agents in the treatment of UTIs, and they are more expensive. These agents are not active against enterococci
Parenteral Therapy			
Aminoglycosides Gentamicin Tobramycin Amikacin	Ototoxicity, nephrotoxicity	Serum creatinine and BUN, serum drug concentrations, and individual pharmacokinetic monitoring	These agents are renally excreted and achieve good concentrations in the urine. Amikacin generally is reserved for multidrug-resistant bacteria
Penicillins			
Ampicillin–sulbactam Piperacillin–tazobactam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	These agents generally are equally effective for susceptible bacteria. The extended-spectrum penicillins are more active against *P. aeruginosa* and enterococci and often are preferred over cephalosporins. They are useful in renally impaired patients or when an aminoglycoside is to be avoided
Cephalosporins			
Ceftriaxone Ceftazidime Cefepime Ceftozolane/tazaobactam Ceftazidime/avabactam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Second- and third-generation cephalosporins have a broad spectrum of activity against gram-negative bacteria, but are not active against enterococci and have limited activity against *P. aeruginosa*. Ceftazidime and cefepime are active against *P. aeruginosa*. They are useful for nosocomial infections and urosepsis due to susceptible pathogens
Carbapenems/monobactams Imipenem–cilistatin Meropenem Meropenem/vaborbactam Doripenem Ertapenem Aztreonam	Hypersensitivity (rash, anaphylaxis), diarrhea, superinfections, and seizures	CBC, signs of rash, or hypersensitivity	Carbapenems have a broad spectrum of activity, including gram-positive, gram-negative, and anaerobic bacteria. Imipenem, meropenem, and doripenem are active against *P. aeruginosa* and enterococci, but ertapenem is not. Aztreonam is a monobactam that is only active against gram-negative bacteria, including some strains of *P. aeruginosa*. Generally useful for nosocomial infections when aminoglycosides are to be avoided and in penicillin-sensitive patients
Fluoroquinolones Ciprofloxacin Levofloxacin	Hypersensitivity, photosensitivity, GI symptoms,	CBC, baseline serum creatinine, and	These agents have broad-spectrum activity against both gram-negative and gram-positive bacteria. They provide urine and high-tissue concentrations and are actively secreted in reduced renal function

	dizziness, confusion, and tendonitis (black box warning)	BUN	

BUN, blood urea nitrogen; CBC, complete blood count; GI, gastrointestinal; UTIs, urinary tract infections.

TABLE 139-3

Overview of Outpatient Antimicrobial Therapy for Lower Tract Infections in Adults

Indications	Antibiotic	Oral Dose	Interval[a]	Duration
Lower tract infections				
Uncomplicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	3 days
	Nitrofurantoin monohydrate	100 mg	Twice a day	5 days
	Fosfomycin trometamol	3 g	Single dose	1 day
	Ciprofloxacin	250 mg	Twice a day	3 days
	Levofloxacin	250 mg	Once a day	3 days
	Amoxicillin–clavulanate Pivmecillinam	500 mg 400 mg	Every 8 hours Twice a day	5-7 days 3 days
Complicated	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	7-10 days
	Ciprofloxacin	250-500 mg	Twice a day	7-10 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	7-10 days
Recurrent infections	Nitrofurantoin	50 mg	Once a day	6 months
	Trimethoprim–sulfamethoxazole	1/2 SS tablet	Once a day	6 months
Acute pyelonephritis	Trimethoprim–sulfamethoxazole	1 DS tablet	Twice a day	14 days
	Ciprofloxacin	500 mg	Twice a day	14 days
		1,000 mg ER	Once a day	7 days
	Levofloxacin	250 mg	Once a day	10 days
		750 mg	Once a day	5 days
	Amoxicillin–clavulanate	500 mg	Every 8 hours	14 days

DS, double strength; SS, single strength.

[a] Dosing intervals for normal renal function.

TABLE 139-4

Evidence-Based Empirical Treatment of UTIs and Prostatitis

Diagnosis	Pathogens	Treatment Recommendation	Comments
Acute uncomplicated cystitis	*Escherichia coli*, *Staphylococcus saprophyticus*	1. Nitrofurantoin × 5 days (A,I)[m] 2. Trimethoprim–sulfamethoxazole × 3 days (A,I)[a] 3. Fosfomycin trometamol × 1 dose (A,I)[a] 4. Fluoroquinolone × 3 days (A,I)[a] 5. *β*-Lactams × 3-7 days (B,I)[a] 6. Pivmecillinam × 3-7 days (A,I)	Short-course therapy more effective than single dose Reserve fluoroquinolones as alternatives to development of resistance (A-III)[a] β-Lactams as a group are not as effective in acute cystitis then trimethoprim–sulfamethoxazole or the fluoroquinolones, do not use amoxicillin or ampicillin[a] Pivmecillinam not available in United States
Pregnancy	As above	1. Amoxicillin–clavulanate × 7 days 2. Cephalosporin × 7 days 3. Trimethoprim–sulfamethoxazole × 7 days	Avoid trimethoprim–sulfamethoxazole during the third trimester
Acute pyelonephritis			
Uncomplicated	*E. coli*	1. Quinolone × 7 days (A,I)[a] 2. Trimethoprim–sulfamethoxazole (if susceptible) × 14 days (A,I)[a]	Can be managed as outpatient
	Gram-positive bacteria	1. Amoxicillin or amoxicillin–clavulanic acid × 14 days	
Complicated	*E. coli* *P. mirabilis* *K. pneumoniae* *P. aeruginosa* *Enterococcus faecalis*	1. Quinolone × 14 days 2. Extended-spectrum penicillin plus aminoglycoside	Severity of illness will determine duration of IV therapy; culture results should direct therapy Oral therapy may complete 14 days of therapy
Prostatitis	*E. coli* *K. pneumoniae* *Proteus* spp. *P. aeruginosa*	1. Trimethoprim–sulfamethoxazole × 4-6 weeks 2. Quinolone × 4-6 weeks	Acute prostatitis may require IV therapy initially Chronic prostatitis may require longer treatment periods or surgery

UTI, urinary tract infection.

[a] Strength of recommendations: A, good evidence for; B, moderate evidence for; C, poor evidence for and against; D, moderate against; E, good evidence against. Quality of evidence: I, at least one proper randomized, controlled study; II, one well-designed clinical trial; III, evidence from opinions, clinical experience, and expert committees.

Data from Reference 1.

8 The therapeutic management of UTIs is best accomplished by first categorizing the type of infection: acute uncomplicated cystitis, symptomatic abacteriuria, ASB, complicated UTIs, recurrent infections, or prostatitis. In choosing the appropriate antibiotic therapy, aware of the increasing resistance of *E. coli* and other pathogens to many frequently prescribed antimicrobials.[44] Resistance to *E. coli* is as high as 37% for amoxicillin and ampicillin.[1,45] Most *E. coli* remain susceptible to trimethoprim–sulfamethoxazole, although resistance is continuing to increase and has been reported as high as 27%.[46] Although resistance to the fluoroquinolones remains low, these agents are being used more frequently and the incidence of fluoroquinolone-resistant *E. coli* is increasingly being reported and is of great concern.[45–51] Current or recent antibiotic exposure is the most significant risk factor associated with *E. coli* resistance and with the extensive use of the fluoroquinolones and trimethoprim–sulfamethoxazole for various infections, including UTIs, resistance will continue to increase.[45–50] In addition, broad-spectrum antimicrobials such as fluoroquinolones and broad-spectrum cephalosporins have a high impact on GI flora, increasing the risk of collateral damage (term used to refer to ecological adverse effects of antibiotic therapy) or the selection of resistant *E. coli* pathogens.[45–48,51,52] In light of rising resistance and in order to decrease the overuse of broad-spectrum antimicrobials, agents such as nitrofurantoin and fosfomycin are now considered first-line treatments along with trimethoprim–sulfamethoxazole in acute uncomplicated cystitis. Both nitrofurantoin and fosfomycin have little effects on the gut flora and *E. coli* susceptibility still remains high.[52–56] With the increased use of nitrofurantoin and fosfomycin since the 2010 guidelines, clinicians are starting to evaluate the success rate of resolution of uncomplicated lower UTIs in women when single-dose fosfomycin versus nitrofurantoin are used. More research will need to be done to establish that one therapy is more effective than the other.[57] Antibiotic therapy should be determined based on the geographic resistance patterns, as well as the patient's recent history of antibiotic exposure.

Acute Uncomplicated Cystitis

Acute uncomplicated cystitis is the most common form of UTI. These infections typically occur in females of childbearing age and often are related to sexual activity. Although the presence of dysuria, frequency, urgency, and suprapubic discomfort frequently is associated with lower tract infection, a significant number of patients have upper tract involvement as well.[3] Because these infections are predominantly caused by *E. coli*, antimicrobial therapy initially should be directed against this organism. Other common causes include *S. saprophyticus* and occasionally *K. pneumoniae* and *Proteus mirabilis*. Because the causative organisms and their susceptibility generally are known, many clinicians advocate a cost-effective approach to management. This approach includes a urinalysis and initiation of empirical therapy without a urine culture (Fig. 139-1).[1] Therefore, the susceptibility patterns of the geographic area drive the choice of empiric therapy.

The goal of treatment for uncomplicated cystitis is to eradicate the causative organism and to reduce the incidence of recurrence caused by relapse or reinfection. The ability to reduce the chance of recurrence depends on the agent's efficacy in eradicating the uropathogenic bacteria from the vaginal and GI reservoir. In the past, conventional therapy consisted of an effective oral antibiotic administered for 7 to 14 days. However, acute cystitis is a superficial mucosal infection that can be eradicated with much shorter courses of therapy (3 days). Advantages of short-course therapy include increased adherence, fewer side effects, decreased cost, and less potential for the development of resistance.

⑦Three-day courses of trimethoprim–sulfamethoxazole or a fluoroquinolone (eg, ciprofloxacin or levofloxacin, not moxifloxacin) are superior to single-dose therapies.[55,58–60] Although the fluoroquinolones have shown excellent efficacy in acute cystitis, the guidelines recommend reserving these agents for patients with suspected or possible pyelonephritis due to the collateral damage risk. Instead, a 3-day course of trimethoprim–sulfamethoxazole, a 5-day course of nitrofurantoin, or a one-time dose of fosfomycin should be considered as first-line therapy.[1,53–61] In areas where there is more than 20% resistance of *E. coli* to trimethoprim–sulfamethoxazole, nitrofurantoin or fosfomycin should be used. Amoxicillin or ampicillin should not be used due to the high incidence of resistant *E. coli*. Instead, if a β-lactam must be used, amoxicillin–clavulanate, cefdinir, cefaclor, or cefpodoxime proxetil for 3 to 7 days are the preferred choices. For most adult females, short-course therapy is the treatment of choice for uncomplicated lower UTIs. Short-course therapy is inappropriate for patients who have had previous infections caused by resistant bacteria, for male patients, and for patients with complicated UTIs. If symptoms recur or do not respond to therapy, a urine culture should be obtained and conventional therapy with a suitable agent instituted.[1]

Symptomatic Abacteriuria

Symptomatic abacteriuria or acute urethral syndrome represents a clinical syndrome in which females present with dysuria and pyuria, but the urine culture reveals less than 10^5 bacteria/mL (10^8/L) of urine. Acute urethral syndrome accounts for more than half the complaints of dysuria seen in the community today. Infections typically involve small numbers of coliform bacteria, including *E. coli*, *Staphylococcus* spp., or *Chlamydia trachomatis*. Additional causes include *Neisseria gonorrhoeae*, *Gardnerella vaginalis*, and *Ureaplasma urealyticum.*

Most patients presenting with pyuria will, in fact, have infection that requires treatment. If antimicrobial therapy is ineffective, a culture should be obtained. If the patient reports recent sexual activity, therapy for *C. trachomatis* should be considered. Chlamydial treatment should consist of 1 g azithromycin or doxycycline 100 mg twice daily for 7 days. Often, concomitant treatment of all sexual partners is required to cure chlamydial infections and prevent reacquisition (see Chapter 140, “Sexually Transmitted Diseases”).

Asymptomatic Bacteriuria

ASB is the finding of two consecutive urine cultures with more than 10^5 organisms/mL (10^8/L) of the same organism in the absence of urinary symptoms. Most patients with ASB are older females. Also, pregnant females frequently present with ASB. Although these individuals typically respond to treatment, relapse and reinfection are common and chronic ASB is difficult to eradicate.

The management of ASB depends on the age of the patient and whether or not the person is pregnant. In children, because of a greater risk of developing renal scarring and long-standing renal damage, treatment should consist of the same conventional courses of therapy as used for symptomatic infection. The greatest risk of renal damage occurs during the first 5 years of life.[62–63] In nonpregnant females, therapy is controversial; however, treatment has little effect on the natural course of infections. Two groups characterize ASB in the elderly: those with persistent bacteriuria and those with intermittent bacteriuria.

Several studies in hospitalized older adults, however, have not found antimicrobial therapy to be efficacious for abacteruria.[64–67] Thorough investigation of other causes of acute functional or cognitive changes or decline that may point to possible infection is encouraged in order to avoid unnecessary use of antibiotics which may lead to adverse consequences. However, persons with bacteriuria along with other systemic signs suggesting severe infection should be treated empirically with broad spectrum antimicrobial therapy until other causes are ruled out.[64] A number of questions remain unanswered due to limited data. For example: What is the effect of eradication of bacteriuria on life expectancy? What are the cost-effectiveness and risk-to-benefit ratio of therapy? What is the effect on morbidity? Certainly with the information available and the high adverse reaction rate in the elderly, vigorous treatment and screening programs cannot be advocated.

Complicated Urinary Tract Infections

Acute Pyelonephritis

A presentation of high-grade fever (more than 38.3°C [100.9°F]) and severe flank pain should be treated as acute pyelonephritis and warrants aggressive management. Severely ill patients with pyelonephritis should be hospitalized and IV antimicrobials administered initially (see Table 139-4). However, milder cases may be managed with orally administered antibiotics in an outpatient setting. Signs and symptoms of nausea, vomiting, and dehydration may require hospitalization.

At the time of presentation, a Gram stain of the urine should be performed along with a urinalysis, culture, and sensitivity tests. The Gram stain should indicate the morphology of the infecting organism(s) and help direct the selection of an appropriate antibiotic. However, the precise identity and susceptibility of the infecting organism(s) will be unknown initially, warranting empirical therapy. The goals of treatment include the achievement of therapeutic concentrations of an antimicrobial agent in the bloodstream and urinary tract to which the invading organism is susceptible and sufficient therapy to eradicate residual infection in the tissues of the urinary tract.

In the mild-to-moderate symptomatic patient in whom oral therapy is considered, an effective agent should be administered for 7 to 14 days, depending on the agent used.[1,68–73] Oral antibiotics that are highly active against the probable pathogens and that are sufficiently bioavailable are preferred. Fluoroquinolones (ciprofloxacin or levofloxacin) orally for 7 to 10 days are the first-line choice in mild-to-moderate pyelonephritis. Other options include trimethoprim–sulfamethoxazole for 14 days. If amoxicillin–clavulanate or an oral cephalosporin is used, it is recommended to give an initial long-acting parenteral antimicrobial such as ceftriaxone first and continue the oral agent for 10 to 14 days. If a Gram stain reveals gram-positive cocci, *Enterococcus faecalis* should be considered and treatment directed against this potential pathogen (ampicillin). Close follow-up of outpatient treatment is mandatory to ensure success.

In the seriously ill patient, parenteral therapy should be administered initially. Therapy should provide a broad spectrum of coverage and should be directed toward bacteremia or sepsis, if present. A number of antibiotic regimens have been used as empirical therapy, including an IV fluoroquinolone, an aminoglycoside with or without ampicillin, and extended-spectrum cephalosporins with or without an aminoglycoside and carbapenems.[1,74] Other options include aztreonam, the β-lactamase inhibitor combinations (eg, ampicillin–sulbactam, piperacillin–tazobactam, cetazidime/avabactam and cefetolozone/tazobactam), carbapenems (eg, imipenem, meropenem, doripenem, or ertapenem), novel boronic acid-based beta-lactamase inhibitor (eg, meropenem-vaborbactam), and IV trimethoprim–sulfamethoxazole.[74–76] If the patient has been hospitalized within the past 6 months, has a urinary catheter, or is a nursing home resident, the possibility of *P. aeruginosa* and enterococci, as well as multiple resistant organisms, should be considered. In this setting, broader spectrum coverage is recommended such as an extended spectrum beta-lactam/beta-lactamase inhibitor or carbapenem. Ertapenem should not be used in this situation owing to its inactivity against enterococci and *P. aeruginosa*.[72]

Effective therapy should stabilize the patient within 12 to 24 hours. A significant reduction in urine bacterial concentrations should occur in 48 hours. If bacteriologic response has not occurred, an alternative agent should be considered based on susceptibility testing. If the patient fails to respond clinically within 3 to 4 days or has persistently positive blood or urine cultures, further investigation is needed to exclude bacterial resistance, possible obstruction, papillary necrosis, intrarenal or perinephric abscess, or some other disease process. Usually by the third day of therapy, the patient is afebrile and significantly less symptomatic. In general, after the patient has been afebrile for 24 hours, parenteral therapy may be discontinued and oral therapy instituted to complete a 2-week course. Follow-up urine cultures should be obtained 2 weeks after completion of therapy to ensure a satisfactory response and detect possible relapse.

Urinary Tract Infections in Males

The management of UTIs in males is distinctly different and often more difficult than in females. Infections in male patients are considered to be complicated because endogenous bacteria in the presence of functional and/or structural abnormalities that disrupt the normal defense mechanisms of the urinary tract cause them. The incidence of infections in males younger than 60 years is much less than the incidence in females. During the adult years, the occurrence of infection can be related directly to some manipulation of the urinary tract. The most common causes are instrumentation of the urinary tract, catheterization, and renal and urinary stones. Uncomplicated infections are rare, but they may occur in young males as a result of homosexual activity, noncircumcision, and having sex with partners who are colonized with uropathogenic bacteria. As the patient ages, the most common cause of infection is related to bladder outlet obstruction because of prostatic hypertrophy. In addition, the prostate gland may become infected and provide a nidus for recurrent infection in males.

The conventional view is that therapy in males requires prolonged treatment (Fig. 139-2). A urine culture should be obtained before treatment because the cause of infection in males is not as predictable as in females. Single-dose or short-course therapy is not recommended in males. Considerably fewer data are available comparing various antimicrobial agents in males as compared with females. If gram-negative bacteria are presumed, trimethoprim–sulfamethoxazole or the quinolone antimicrobials should be considered because these agents achieve high renal tissue, urine, and prostatic concentrations.[77]

Initial therapy should be for 10 to 14 days. Factors associated with treatment success are isolation of a single organism, the absence of significant obstruction or anatomic abnormalities, a normally functioning urinary tract, and the absence of prostatic involvement. Parenteral therapy may be required in certain situations, such as in severely ill patients, in the presence of acute prostatitis or epididymitis and in patients who cannot tolerate oral medications. A comparison of 2-week versus 6-week therapy in males with recurrent infections who were given trimethoprim–sulfamethoxazole had cure rates of 29% and 62%, respectively.[78] Other investigators advocate longer treatment periods in males, as well.[79] Follow-up cultures at 4 to 6 weeks after treatment are important in males to ensure bacteriologic cure. Many patients require longer periods of treatment and possible alterations in antibiotics, depending on culture and sensitivity results and clinical response.

Recurrent Infections

Recurrent episodes of UTI account for a significant portion of all UTIs. Of the individuals suffering from recurrent infections, 80% can be considered reinfections, that is, the recurrence of infection by an organism different from the organism isolated from the preceding infection. These persons most commonly are females and recurrence develops in approximately 20% of females with cystitis. Reinfections can be divided into two groups: those with less than three episodes per year and those who develop more frequent infections. Treatment strategies are continuing to develop, as well as, an understanding of the role of the microbiome.[80,81] An excellent overview of the various treatment modalities for recurrent UTI in females has been published.[81]

Management strategies depend on predisposing factors, number of episodes per year, and the person's preference. Factors commonly associated with recurrent infections include sexual intercourse and diaphragm or spermicide use for birth control. Therapeutic options include self-administered therapy, postcoital therapy, and continuous low-dose prophylaxis. In persons with infrequent infections (less than three infections per year), each episode may be treated as a separately occurring infection. Short-course therapy is appropriate in this setting. Many females have been treated successfully with self-administered short-course therapy at the onset of symptoms.[43,83]

In persons with more frequent symptomatic infections and no apparent precipitating event, long-term prophylactic antimicrobial therapy may be instituted. Prophylactic therapy reduces the frequency of symptomatic infections in older males and females, and children. In females, most studies show a reinfection rate of two to three per patient-year reduced to 0.1 to 0.2 per patient-year with treatment.[83] Before prophylaxis is initiated, individuals should be treated conventionally with an appropriate agent. Trimethoprim–sulfamethoxazole (one-half of a single-strength tablet), trimethoprim (100 mg daily), fluoroquinolone (levofloxacin 500 mg daily), and nitrofurantoin (50 or 100 mg daily) all reduce the rate of reinfection as the single-agent therapy.[83] Full-dose therapy with these agents is unnecessary and single daily doses can be used. Therapy generally is prescribed for a period of 6 months, during which time urine cultures are followed monthly. If symptomatic episodes develop, the patient should receive a full course of therapy with an effective agent and then resume prophylactic therapy. Therapy with methenamine hippurate for short-term use may be beneficial, but its overall utility is not well documented, especially for long-term prophylaxis.[84] In females who experience symptomatic reinfections in association with sexual activity, voiding after intercourse may help prevent infection. Also, single-dose prophylactic therapy with trimethoprim–sulfamethoxazole taken after intercourse reduces the incidence of recurrent infection significantly.[83]

In postmenopausal females with recurrent infections, the lack of estrogen results in changes in the bacterial flora of the vagina, resulting in increased colonization with uropathogenic *E. coli*. Topically administered estrogen cream reduces the incidence of infections in this population.[18,19]

The remaining 20% of recurrent UTIs are relapses, that is, persistence of infection with the same organism after therapy for an isolated UTI. The recurrence of symptomatic or ASB after therapy usually indicates that the person has renal involvement, a structural abnormality of the urinary tract or chronic bacterial prostatitis. In the absence of structural abnormalities, relapse often is related to renal infection and requires a long duration of treatment. Females who relapse after short-course therapy should receive a 2-week course of therapy. In patients who relapse after 2 weeks of therapy, therapy should be continued for another 2 to 4 weeks. If relapse occurs after 6 weeks of therapy, urologic evaluation should be performed and any obstructive lesion should be corrected. If this is not possible, therapy for 6 months or longer may be considered. Asymptomatic adults who have no evidence of urinary obstruction should not receive long-term therapy.

In males, relapse usually indicates bacterial prostatitis, the most common cause of persistent bacteriuria. Although many agents have been used for long-term therapy of relapses, trimethoprim–sulfamethoxazole and the fluoroquinolones appear to be highly effective.

Special Conditions

Urinary Tract Infections in Pregnancy

During pregnancy, significant physiologic changes occur to the entire urinary tract that dramatically alter the prevalence of UTIs and pyelonephritis. Severe dilation of the renal pelvis and ureters, decreased ureteral peristalsis, and reduced bladder tone occur during pregnancy.[86] These changes result in urinary stasis and reduced defenses against reflux of bacteria to the kidneys. In addition, increased urine content of amino acids, vitamins, and nutrients encourages bacterial growth. All of these factors increase the incidence of bacteriuria resulting in symptomatic infections, especially during the third trimester.

ASB occurs in 4% to 7% of pregnant persons. Of whom, 20% to 40% will develop acute symptomatic pyelonephritis during pregnancy. If untreated, ASB has the potential to cause significant adverse effects, including prematurity, low birth weight, and stillbirth.[86,87] Because pyelonephritis is associated with significant adverse events during pregnancy, routine screening tests for bacteriuria should be performed at the initial prenatal visit and again at 28 weeks gestation. In persons with significant bacteriuria, symptomatic or asymptomatic, treatment is recommended so as to avoid possible complications. Organisms associated with bacteriuria are the same as those seen in uncomplicated UTIs with *E. coli* isolated most frequently.

Therapy should consist of an agent administered for 7 days that has a relatively low adverse effect potential and is safe for the mother and baby. The administration of amoxicillin, amoxicillin–clavulanate, or cephalexin is effective in 70% to 80% of patients. Nitrofurantoin has been used in pregnancy; however, it must be used with caution as occurrences of birth defects have been reported. Tetracyclines should be avoided because of teratogenic effects and sulfonamides should not be administered during the third trimester because of the possible development of kernicterus and hyperbilirubinemia. In addition, fluoroquinolones should not be given because of their potential to inhibit cartilage and bone development in the newborn. A follow-up urine culture 1 to 2 weeks after completing therapy and then monthly until gestation is complete is recommended. Optimal treatment for preventing recurrent UTI and ASB has yet to be defined.[89]

Catheterized Patients

The use of an indwelling catheter frequently is associated with infection of the urinary tract and represents the most common cause of hospital-acquired infection. The incidence of catheter-associated infection is related to a variety of factors, including method and duration of catheterization, the catheter system (open or closed), the care of the system, the susceptibility of the patient, and the technique of the healthcare personnel inserting the catheter. Catheter-related infections are reasonably preventable infections and are now considered one of the hospital-acquired complications chosen by the Centers for Medicare and Medicaid Services in which hospitals will no longer receive reimbursement for the treatment.[90,91]

Bacteria may enter the bladder in a number of ways. During the catheterization, bacteria may be introduced directly into the bladder from the urethra. Once the catheter is in place, bacteria may pass up the lumen of the catheter by the movement of air bubbles, motility of the bacteria, or capillary action. In addition, bacteria may reach the bladder from around the exudative sheath that surrounds the catheter in the urethra. Cleaning the periurethral area thoroughly and applying an antiseptic (povidone-iodine) can minimize infection occurring during insertion of the catheter. The use of closed drainage systems has reduced significantly the ability of bacteria to pass up the lumen of the catheter and cause infection. A bacterium passing around the catheter sheath in the urethra is probably the most important pathway for infection. Avoiding manipulation of the catheter and trauma to the urethra and urethral meatus can minimize this path of acquisition.

Persons with indwelling catheters acquire UTIs at a rate of 5% per day.[90–92] The closed systems are capable of preventing bacteriuria in most patients for up to 10 days with appropriate care. After 30 days of catheterization, however, there is a 78% to 95% incidence of bacteriuria, despite use of a closed system.[91,93] Unfortunately, UTI symptoms in a catheterized person are not clearly defined. Fever, peripheral leukocytosis, and urinary signs and symptoms may be of little predictive value.[90,91] When bacteriuria occurs in the asymptomatic, short-term catheterized person (less than 30 days), the use of systemic antibiotics should be withheld and the catheter should be removed as soon as possible. If the person becomes symptomatic, the catheter should be removed and treatment as described for complicated infections started. The optimal duration of therapy is unknown. In the long-term catheterized person (more than 30 days), bacteriuria is inevitable.[90,91] The administration of systemic antibiotics active against the infecting organism will sterilize the urine; however, reinfection occurs rapidly in more than 50% of persons. In addition, resistant organisms recolonize the urine. Symptomatic individuals must be treated because they are at the risk of developing pyelonephritis and bacteremia. Bacteria adhere to the catheter and produce a biofilm consisting of bacterial glycocalyces, Tamm–Horsfall protein, as well as apatite and struvite salts, that act to protect the bacteria from antibiotics.[92] Biofilm mechanisms and their treatment continue to be examined and more fully understood.[93,94] Recatheterization with a new sterile unit should be performed in symptomatic individuals, if the existing catheter has been in place for more than 2 weeks.

Various methods have been proposed to prevent the development of bacteriuria and infection in the patient with an indwelling catheter (see Table 139-4). The success of these methods depends on the type of catheter and the length of time it is in place. The use of constant bladder irrigation with antiseptic or antibacterial solutions reduces the incidence of infection in those with open drainage systems, but this approach has no advantage in those with closed systems. The use of prophylactic systemic antibiotics in persons with short-term catheterization reduces the incidence of infection over the first 4 to 7 days.[91,93] With long-term catheterization, however, antibiotics only postpone the development of bacteriuria and lead to the emergence of resistant organisms. Therefore, antibiotic prophylaxis should not be utilized in short-term or long-term catheterized patients.

PROSTATITIS

Bacterial prostatitis is an inflammation of the prostate gland and surrounding tissue as a result of infection. It is classified as either acute or chronic. By definition, pathogenic bacteria and significant inflammatory cells must be present in prostatic secretions and urine to make the diagnosis of bacterial prostatitis. Prostatitis occurs rarely in young males, but it is commonly associated with recurrent infections in persons older than 30 years. As many as 50% of all males develop some form of prostatitis at some period in their life.[95–97] The acute form typically is an acute infectious disease characterized by a sudden onset of fever, tenderness, and urinary and constitutional symptoms. Chronic prostatitis presents with few symptoms related to the prostate but rather symptoms of urinating difficulty, low back pain, perineal pressure, or a combination of these. It represents a recurring infection with the same organism that results from incomplete eradication of bacteria from the prostate gland.

Pathogenesis and Etiology

The exact mechanism of bacterial infection of the prostate is not well understood. The possible routes of infection are the same as those for UTIs. Reflux of infected urine into the prostate gland is thought to play an important role in causing infection. Intraprostatic reflux of urine occurs commonly and results in direct inoculation of infected urine into the prostate.[95–97] In addition, intraprostatic reflux of sterile urine can result in a chemical prostatitis and may be the cause of nonbacterial prostatitis. Sexual intercourse may contribute to infection of the prostate gland because prostatic secretions from males with chronic prostatitis and vaginal cultures from their sexual partners grow identical organisms. Other known causes of bacterial prostatitis include indwelling urethral and condom catheterization, urethral instrumentation, and transurethral prostatectomy in patients with infected urine.

Physiologic factors are believed to contribute to the development of prostatitis. Functional abnormalities found in bacterial prostatitis include altered prostate secretory functions. Prostatic fluid obtained from normal males contains prostatic antibacterial factor. This heat-stable, low-molecular-weight cation is a zinc-complexed polypeptide that is bactericidal to most urinary tract pathogens.[98] The antibacterial activity of prostatic antibacterial factor is related directly to the zinc content of prostatic fluid. Prostate fluid zinc levels and prostatic antibacterial factor activity also appear diminished in persons with prostatitis, as well as in older males.[98] Whether these changes are a cause or effect of prostatitis remains to be determined.

The pH of prostatic secretions in patients with prostatitis is altered.[99] Normal prostatic secretions have a pH in the range of 6.6 to 7.6. With increasing age, the pH tends to become more alkaline. With inflammation of the prostate, prostatic secretions may have an alkaline pH in the range of 7 to 9. These changes suggest a generalized secretory dysfunction of the prostate that not only can affect the pathogenesis of prostatitis but also can influence the mode of therapy.

Gram-negative enteric organisms are the most frequent pathogens in acute bacterial prostatitis.[95–97] *E. coli* is the predominant organism, occurring in 75% of cases. Other gram-negative organisms frequently isolated include *K. pneumoniae*, *P. mirabilis*, and less frequently, *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp. Infrequently, cases of gonococcal and staphylococcal prostatitis occur. *E. coli* most commonly causes chronic bacterial prostatitis with other gram-negative organisms isolated less frequently. The importance of gram-positive organisms in chronic bacterial prostatitis remains controversial. *S. epidermidis*, *S. aureus*, and diphtheroids have been isolated.

Clinical Presentation

Acute bacterial prostatitis presents similarly to other acute infections with fever, chills, myalgias, and other typical signs and symptoms. Massage of the prostate will express a purulent discharge that will readily grow the pathogenic organism. Prostatic massage is contraindicated in acute bacterial prostatitis, however, because of the risk of inducing bacteremia and the associated local pain. The diagnosis of acute bacterial prostatitis can be made from the clinical presentation, abdominal, genital, and digital rectal examination, and the presence of significant bacteriuria. As with other UTIs, the infecting organism can be isolated from a midstream specimen.

CLINICAL PRESENTATION: Bacterial Prostatitis

Signs and Symptoms

- Acute bacterial prostatitis: High fever, chills, malaise, myalgia, localized pain (perineal, rectal, sacrococcygeal), frequency, urgency, dysuria, nocturia, and retention
- Chronic bacterial prostatitis: Voiding difficulties (frequency, urgency, dysuria), low back pain, and perineal and suprapubic discomfort

Physical Examination

- Acute bacterial prostatitis: Swollen, tender, tense, or indurated gland
- Chronic bacterial prostatitis: Boggy, indurated (enlarged) prostate in most patients

Laboratory Tests

- Bacteriuria
- Bacteria in EPSs

In contrast, chronic bacterial prostatitis is more difficult to diagnose and treat. Chronic bacterial prostatitis typically is characterized by recurrent UTIs with the same pathogen and is the most common cause of recurrent UTI in males. The patient's clinical presentation can vary widely. Many adults, however, are asymptomatic.

Because physical examination of the prostate is often normal, urinary tract localization studies are critical to the diagnosis of chronic bacterial prostatitis. The method of quantitative localization culture, as described by Meares and Stamey,[15,100] remains the diagnostic standard (Fig. 139-3). The method compares the bacterial growth in sequential urine and prostatic fluid cultures obtained during micturition. The first 10 mL of voided urine is collected (voiding bladder 1, or VB_1) and constitutes urethral urine. After approximately 200 mL of urine has been voided, a 10-mL midstream sample is collected (VB_2). This specimen represents bladder urine. After the person voids, the prostate is massaged and expressed prostatic secretions (EPS) are collected. After prostatic massage, the patient voids again and 10 mL of urine is collected (VB_3).

FIGURE 139-3

Segmented cultures of the lower tract in men. (EPS, expressed prostatic secretions; VB_1, voiding bladder 1; VB_2, voiding bladder 2; VB_3, voiding bladder 3)

The diagnosis of bacterial prostatitis is made when the number of bacteria in EPS is 10 times that of the urethral sample (VB_1) and midstream sample (VB_2). If no EPS is available, the urine sample following massage (VB_3) should contain a bacterial count 10-fold greater than that of VB_1 or VB_2. If significant bacteriuria is present, ampicillin, cephalexin, or nitrofurantoin should be given for 2 to 3 days to sterilize the urine prior to performing the localization study.

Treatment

⑨The goals for the management of bacterial prostatitis are the same as those for UTIs. Acute bacterial prostatitis responds well to appropriate antimicrobial therapy that is directed at the most commonly isolated organisms. Prostatic penetration of antimicrobials occurs because the acute inflammatory reaction alters the cellular membrane barrier between the bloodstream and the prostate. Most patients can be managed with oral antimicrobial agents, such as trimethoprim–sulfamethoxazole and the fluoroquinolones (eg, ciprofloxacin, levofloxacin) (see Table 139-4). Other effective agents in this setting include cephalosporins and β-lactam–β-lactamase combinations. Although IV therapy is rarely necessary for total treatment, IV to oral sequential therapy with trimethoprim–sulfamethoxazole or the fluoroquinolones is appropriate. Most patients will become afebrile within 36 hours of antibiotic treatments.[96] The conversion to an oral antibiotic can be considered after the patient is afebrile for 48 hours or after 3 to 5 days of IV therapy. The total course of antibiotic therapy should be 4 weeks in order to reduce the risk of development of chronic prostatitis, although in some cases 2 weeks may be sufficient. Therapy may be prolonged with chronic prostatitis (6-12 weeks). Long-term suppressive therapy also may be initiated for recurrent infections, such as three times weekly ciprofloxacin, trimethoprim–sulfamethoxazole regular-strength tablet daily, or nitrofurantoin 100 mg daily.[100]

Chronic bacterial prostatitis often presents a more vexing situation because cures are obtained rarely. Despite high serum concentrations of antibacterial drugs in excess of the minimal inhibitory concentrations of the infecting organisms, bacteria persist in prostatic fluid. Most likely the failure to eradicate sensitive bacteria is caused by the inability of antibiotics to reach sufficient concentrations in the prostatic fluid and cross the prostatic epithelium.

Several factors that determine antibiotic diffusion into prostatic secretions were delineated from the canine model. Lipid solubility is a major determinant in the ability of drugs to diffuse from plasma across epithelial membranes. The degree of ionization in plasma also affects the diffusion of drugs. Only unionized molecules can cross the lipid barrier of prostatic cells, and the drug's pK_a (negative logarithm of acid ionization constant) directly determines the fraction of unchanged drug.

The pH gradient across the membrane has an influence on tissue penetration, as well. A pH gradient of at least one pH unit between separate compartments allows for ion trapping. As the unionized drug crosses the epithelial barrier into prostatic fluid, it becomes ionized allowing less drug to diffuse back across the lipid barrier. In early studies with the canine model, the prostatic pH was acidic (6.4).[99] In humans, however, the pH of prostatic secretions from an inflamed prostate is actually basic (8.1-8.3).[99]

The choice of antibiotics in chronic bacterial prostatitis should include agents that are capable of reaching therapeutic concentrations in the prostatic fluid and which possess the spectrum of activity to be effective. Agents that achieve therapeutic prostatic concentrations include trimethoprim and the fluoroquinolones. Sulfamethoxazole penetrates poorly and probably contributes little to trimethoprim activity when used in combination. The fluoroquinolones appear to provide the best therapeutic options in the management of chronic bacterial prostatitis. Therapy should be continued for 4 to 6 weeks initially. Longer treatment periods may be necessary in some cases. If therapy fails with these regimens, chronic suppressive therapy may be used or surgery considered.

ANSWERS FOR BEYOND THE BOOK

1. **Correct answer**: Yes, pregnant females should be screened for ASB and treated if it is present. *(Reference: Asymptomatic Bacteriuria Guidelines)*

2. **Correct answer C:** Pyuria and leukocyte esterase can be found in the urinalysis of patients with or without a urinary tract infection but do not increase their risk for a complicated UTI. Age is not a specific risk factor associated with an increase in complicated UTI. Pregnancy does increase the risk of complicated UTI due to anatomical changes and host factors during pregnancy.

3. **Correct answer D:** Ciprofloxacin not appropriate due to concerns about safety and risk to fetus during pregnancy. Not treating is inappropriate due to potential complications of urinary tract infections in pregnancy, specifically pyelonephritis, premature birth, and low birth weight. Trimethoprim/Sulfamethoxazole would be an appropriate choice, especially since she in in her second trimester, but the treatment would only be for 3 days. Nitrofurantoin has clinical experience and is relatively safe in pregnancy, especially after the first trimester.

4. **Correct answer A:** The patient is now showing signs of pyelonephritis with the fever and back pain, so longer treatment would be necessary. Therefore, longer treatment would be required than the 7 days of nitrofurantoin. In addition, pyelonephritis is not isolated in the bladder so you would need an agent that gets blood and tissue concentrations. Levofloxacin like ciprofloxacin is an fluoroquinolone and is therefore inappropriate due to concerns about safety and risk to fetus during pregnancy. The patient can be treated with oral therapy in an outpatient setting, so piperacillin/tazobactam intravenous would not be appropriate and is too broad spectrum for this sensitive *E. coli*. Trimethoprim/Sulfamethoxazole would be an appropriate choice, especially since she in in her second trimester, and is given orally for outpatient therapy. Fourteen days would be the appropriate length of treatment.

ABBREVIATIONS

ASB	asymptomatic bacteriuria
CFU	colony-forming unit
EPS	expressed prostatic secretions
GI	gastrointestinal
PMN	polymorphonuclear leukocyte
UTI	urinary tract infection
WBC	white blood cell

SELF-ASSESSMENT QUESTIONS

1. Which of the following would be categorized as an uncomplicated urinary tract infection?

A. An acute infection involving the lower urinary tract of a 17-year-old girl

B. An acute infection with involvement of the kidneys of a 24-year-old male

C. An acute recurrent infection involving the lower urinary tract of a 58-year-old female

D. An acute infection with involvement of the kidneys of a 75-year-old male

2. When treating a community-acquired UTI in a treatment naive patient who has never had a UTI before, which of the following organisms should be most highly suspected and targeted when choosing antibiotic therapy?

A. *Proteus mirabilis*

B. *Staphylococcus saprophyticus*

C. *Escherichia coli*

D. *Enterococcus faecalis*

3. Which of the following patients is most likely to have a complicated UTI?

A. A 40-year-old healthy woman with hypertension

B. A 30-year-old healthy woman with GERD

C. A 19-year-old healthy woman who has a urethral stricture

D. A 10-year-old healthy girl with no medical issues

4. Which of the following host factors specifically inhibit bacterial growth in the urinary tract of male patients?

A. Osmolality of the urine

B. Prostatic secretions in the urine

C. Urea concentration in the urine

D. pH of the urine

5. JT is a 34-year-old woman who presents to her primary care clinic with fever, dysuria, flank pain, urgency, and vomiting. Which of her symptoms should make the healthcare provider caring for JT suspect that she has a urinary tract infection that has migrated to her upper genitourinary tract?

A. Fever, dysuria

B. Dysuria, urgency

C. Fever, urgency

D. Flank pain, vomiting

6. An 89-year-old male presents to the emergency department with altered mental status, dehydration, and acute kidney injury. His symptoms are attributed to an acute urinary tract infection and he is started on appropriate antibiotics. Which of the following symptoms would his family see the most drastic change in once antibiotics are started?

A. Mental status

B. Kidney function

C. Electrolyte levels

D. Urine amount

7. Altered mental status, change in eating habits, or gastrointestinal (GI) symptoms as opposed to typical manifestations of UTIs are frequently seen in which patient population?

A. Children

B. Elderly

C. Pregnant females

D. Males

8. Which of the following methods of urine collection is best for patients who are unable to void urine?

A. Midstream catch

B. Urine catch using the first 20 to 30 mL of urine flow

C. Catheterization

D. Suprapubic bladder aspiration

9. Which of the following results is most indicative that there is significant bacteria in the urine?

A. Hematuria

B. 10 white blood cell (WBC)/mm^3 (10×10^6/L)

C. More than 10^5 CFU/mL (10^8 CFU/L)

D. Leukocyte esterase positive

10. A 20-year-old woman is diagnosed with uncomplicated cystitis. She has no known drug allergies. Based on the 2010 IDSA Guidelines, which of the following regimens would be the most appropriate treatment for this patient?

A. Ciprofloxacin 500 mg orally twice daily for 3 days

B. Nitrofurantoin 100 mg orally twice daily for 5 days

C. Amoxicillin 500 mg orally four times daily for 3 days

D. Trimethoprim–sulfamethoxazole double strength, 1 tablet orally, 1 dose

11. A 50-year-old woman is admitted to the ICU with severe pyelonephritis. She has a history of anaphylaxis with penicillin. What would be the most appropriate empiric treatment?

A. Trimethoprim–sulfamethoxazole double strength, 1 tablet orally twice daily for 3 days

B. Nitrofurantoin 100 mg orally twice daily for 7 days

C. Cipofloxacin 400 mg IV twice daily for 3 days, followed by 500 mg orally twice daily for 11 days

D. Piperacillin/tazobactam 3.375 g IV q6 hours x 14 days

12. A 34-year-old woman is diagnosed with her third incidence of uncomplicated cystitis in the last 18 months. The trimethoprim–sulfamethoxazole resistance rate for *E.coli* is 10% in the community. Her last prescription filled was TMP/SMX and was completed 30 days ago. Which of the following would be the best choice treatment of an uncomplicated UTI for this patient?

A. Trimethoprim–sulfamethoxazole double strength, one tablet orally twice daily for 3 days

B. Amoxicillin 500 mg orally twice daily for 5 days

C. Fosfomycin 3 gm orally daily for 3 days

D. Ciprofloxacin 500 mg orally twice daily for 5 days

13. A 54-year-old man is diagnosed with acute bacterial prostatitis for the first time. He is an otherwise healthy male with a documented allergy to trimethoprim–sulfamethoxazole. Which of the following is the most appropriate therapy for this patient?

A. Ciprofloxacin 500 mg orally twice daily for 3 days

B. Trimethoprim–sulfamethoxazole double strength, one tablet orally twice daily for 4 weeks

C. Ciprofloxacin 500 mg orally twice daily for 4 weeks

D. Nitrofurantoin 100 mg orally twice daily for 5 days

14. Which of the following antibiotic agents should be avoided in all cases for the treatment of acute uncomplicated cystitis due to antimicrobial resistance?

A. Amoxicillin

B. Levofloxacin

C. Trimethoprim–sulfamethoxazole

D. Nitrofurantoin

15. A 24-year-old woman would like to know what she can do for her frequent UTIs. She notices that she mainly gets them after sexual intercourse. What would be the best recommendation to try first for this patient?

A. Drink cranberry juice daily

B. Levofloxacin 500 mg daily for 1 year

C. Topical estrogen cream

D. Urine voiding after intercourse

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Acute uncomplicated cystitis typically occurs in women of childbearing age and often typically involves the lower urinary tract

2. **C.** The most common cause of uncomplicated UTIs is Escherichia coli, which accounts for 80% to 90% of community-acquired infections. Additional causative organisms in uncomplicated infections include *Staphylococcus saprophyticus*, *Klebsiella* pneumoniae, *Proteus* spp., *Pseudomonas aeruginosa*, and *Enterococcus* spp.[11]

3. **C.** In this question because all patients are females, relatively young and have comorbidities unrelated to the urinary tract, the young woman with a urethral stricture is most likely to have a complicated UTI due to pre-disposing factors that increase her risk of infection of the urinary tract.

4. **B.** Although osmolality, urea concentration, and pH of the urine can help inhibit bacterial growth in the urine, prostatic secretions are specific to male patients and have been shown to inhibit bacterial growth in the urine.

5. **D.** Although patients with upper UTIs present with fever, dysuria, and urgency, the flank pain and vomiting are more specific to the upper GU tract involvement.

6. **A.** In the elderly population, patient's often present with unconventional symptoms when they have a UTI, including mental status change, GI issues (nausea/vomiting), etc. Patient's family members notice this most often, rather than changes in kidney function, electrolyte levels, and urine output which is best measured by a healthcare provider.

7. **B.** In the elderly, change in eating habits or gastrointestinal (GI) symptoms as opposed to typical manifestations of UTIs are frequently. In children, pregnant women, and men, common signs/symptoms include dysuria, urgency, frequency, nocturia, suprapubic heaviness, and gross hematuria.

8. **C.** Catheterization may be necessary for patients who are uncooperative or who are unable to void urine. If catheterization is performed carefully with aseptic technique, the method yields reliable results. Midstream catch is ideal for patients who are able to void on their own and the idea is to catch the urine after the first 20 to 30 mL have been voided to avoid contamination from bacteria that may adhere to the urethra. Suprapubic aspiration is invasive and not recommended as the first attempt to collect urine in those unable to void on their own.

9. **C.** The diagnosis of UTI is based on the isolation of significant numbers of bacteria from a urine specimen. Patients can have pyuria, hematuria, and test positive for leukocyte esterase without having a UTI.

10. **B.** The only viable option is the nitrofurantoin. The dosing and duration of therapy are not in accordance with the 2010 IDSA guidelines for neither TMP/SMX nor amoxicillin. Flouroquinolones would be reserved for the suspicion of more serious infections.

11. **C.** This infection is considered a complicated infection due to the fact that it is pyelonephritis and the patient has been admitted to the ICU. The patient needs 14 days of therapy which is why options A, B, and D are incorrect.

12. **A.** Because the resistance in the community of *E.coli* to trimethoprim-sulfamethoxazole is only 10% and although patient has had prior UTIs because it's been greater than 2 weeks and she has no risk factors. This is a new infection and we would treat it as such. Amoxicillin resistance with *E.coli* is known to be high and not recommended and fosfomycin and cipro would be reserved for patients with more severe infections.

13. **C.** The patient has a documented allergy to TMP/SMX and has never had prostatitis before. Typical therapy would include either a quinolone or TMP/SMX for 4 weeks. Therefore, options A and B are not appropriate for this patient. Patient has a documented serious penicillin allergy that makes D inappropriate as well.

14. **A.** The resistance rate of *E.Coli* to amoxicillin is close to 40% so it should never be used to treat UTI.

15. **D.** The utilization of both estrogen cream and cranberry juice is still somewhat controversial. With resistance increasing, levofloxacin should not be used for prophylaxis. Therefore, urine voiding after intercourse is the best option.

Chapter 140: Sexually Transmitted Infections

Yvonne Burnett; Humberto Jimenez

KEY CONCEPTS

KEY CONCEPTS

① A single dose of ceftriaxone is recommended for uncomplicated gonococcal infections. Antimicrobial stewardship concerns over the impact on the microbiome, increasing rates of azithromycin resistance and continued low ceftriaxone resistance rates, led to the move away from dual drug therapy. If chlamydial infection cannot be excluded, doxycycline should be added.

② Chlamydia genital tract infections represent the most frequently reported communicable disease in the United States. Females are frequently asymptomatic or minimally symptomatic and, if left untreated, may develop complications such as pelvic inflammatory disease (PID), ectopic pregnancy, or infertility. All sexually active females younger than 25 years and women with multiple sexual partners should be screened annually.

③ A 7-day course of metronidazole is the preferred treatment for trichomoniasis in women, with single dose tinidazole as an alternative. Single-dose metronidazole remains the recommended therapy for men.

④ PID treatment should target gonorrhea and chlamydia, with the addition of anaerobic coverage.

⑤ Parenteral penicillin is the treatment of choice for all syphilis infections. Alternative therapies for penicillin-allergic patients are usually suboptimal, have insufficient data, require prolonged oral courses, and/or are not recommended for specific populations. When allergies are reported, clarification of the type of reaction is critical to ensure optimal therapy. For true penicillin allergies, penicillin desensitization protocols are available when penicillin is required.

⑥ Oral acyclovir, famciclovir, and valacyclovir are effective in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Patient-initiated, episodic antiviral therapy started within 1 day of lesion onset or during the prodromal stage preceding an outbreak offers an alternative to continuous suppressive therapy of recurrent infection in some individuals.

⑦ Human papilloma virus (HPV) vaccination reduces complications associated with HPV infection, including development of genital warts and HPV-related cancers. Adolescent vaccination, prior to onset of sexual activity is recommended. Despite robust safety and efficacy data, vaccination rates remain below 80% in target populations.

BEYOND THE BOOK

Obtaining a relevant and culturally sensitive sexual history is an important part of ensuring an individual’s optimal health. Patient interviews should include the five Ps: partners, practices, protection, past STIs, and prevention of pregnancy strategies.

Watch the following videos that focus on the importance of collecting a sexual history and understanding at-risk populations. These videos are useful to enhance student understanding regarding the Collect and Assess steps in the patient care process.

INTRODUCTION

Sexually transmitted infections (STIs) encompass a wide variety of pathogens (Table 140-2), diverse presentations, and continually evolving diagnosis, treatment and prevention strategies. STIs impact short- and long-term health of millions in the United States, yet continue to be underfunded, stigmatized, and devalued as a public health priority. Since 2000, rates continue to rise, with chlamydia doubling, gonorrhea increasing 40%, and primary and secondary syphilis cases soaring fivefold.[1,2] In 2018, one in five people in the United States had an STI.[2] Almost half of the 26 million new infections in 2018 were acquired by teens and young adults (15-24 years old).[1] Besides in youth, STIs rates are disproportionally higher in marginalized groups, specifically sexual and gender minorities (encompassing lesbian, gay, bisexual, and transgender communities), Black, Latinx, American Indian/Alaska Native, and Native Hawaiian/other Pacific Islander people.[1] Furthermore, the financial impact of STIs are substantial, costing the U.S. healthcare system an estimated $16 billion in direct lifetime medical costs.[3]

TABLE 140-2

Sexually Transmitted Diseases

Disease	Associated Pathogens
Bacterial	
Gonorrhea	*Neisseria gonorrhoeae*
Syphilis	*Treponema pallidum*
Chancroid	*Haemophilus ducreyi*
Granuloma inguinale	*Klebsiella granulomatis*
Enteric disease	*Salmonella* spp., *Shigella* spp., *Campylobacter* spp.
Campylobacter infection	*Campylobacter jejuni*
Bacterial vaginosis	*Gardnerella vaginalis, Mycoplasma hominis, Bacteroides* spp., *Mobiluncus* spp.
Chlamydial	
Nongonococcal urethritis	*Chlamydia trachomatis*
Lymphogranuloma venereum	*C. trachomatis*, type L
Viral	
Acquired immunodeficiency syndrome	Human immunodeficiency virus
Herpes genitalis	Herpes simplex virus, types 1 and 2
Viral hepatitis	Hepatitis A, B, C, and D viruses
Condylomata acuminata	Human papillomavirus

Mycoplasmal	
Nongonococcal urethritis	*Mycoplasma genitalium*
Protozoal	
Trichomoniasis	*Trichomonas vaginalis*
Fungal	
Vaginal candidiasis	*Candida albicans*
Parasitic	
Scabies	*Sarcoptes scabiei*
Pediculosis pubis	*Phthirus pubis*
Enterobiasis	*Enterobius vermicularis*

STI health consequences range from urogenital discomfort to encephalitis. Women are especially susceptible to complications, many of which center around reproductive health. Pregnancy-related morbidity is often devastating, including stillbirth and fetal or newborn transmission. Men can also experience reproductive sequelae. Extragenital manifestations, such as neurosyphilis and septic arthritis, can be classic findings or present with non-specific symptoms.

While the terms sexually transmitted diseases (STDs) and STIs are often used interchangeably, there has been a global shift toward using the term STI. Many infections are asymptomatic, with some clearing spontaneously. An STD is a recognizable disease or condition that develops from an STI. Thus, the term STI is more accurate, more inclusive, and carries less stigma than STD.[4]

The risk of acquiring and transmitting an STI varies based on pathogen, host characteristics, local epidemiology, individual behavior, sexual networks, and broader social and structural factors. Age-specific STI rates are historically higher in men versus women; however, reported rates may not represent true gender differences and may reflect ease of detection in men. In recent years, male-to-female ratios for most STIs have declined or reversed, reflecting improved STI screening. Rates of some STIs, such as syphilis and HIV, are disproportionately greater in men who have sex with men (MSM).[1] The risks of acquiring select STIs are elevated among racial and ethnic minorities in the United States, particularly, chlamydia, gonorrhea, and (primary and secondary) syphilis rates among Black versus White Americans.[5] Multiple or anonymous sex partners, condomless sex, and sex while under the influence of drugs or alcohol can increase STI (and HIV) acquisition risks.[6] Limited access and reduced engagement with medical care, living in areas with high prevalence, high-risk sexual networks, and marginalized and/or stigmatized communities are broader factors that can increase STI risk.[7]

The national strategy toward addressing STIs has historically centered on screening, treating, and preventing infections based on individual risks and/or behaviors. These tactics, combined with the complexities of the US healthcare system, societal discomfort discussing sexuality and sexual health, and structural inequities, have led to some of the highest STI rates among higher-income nations. Healthcare provider's implicit bias and systemic discriminatory policies have also hampered efforts to reduce STIs through suboptimal screening initiatives and limited engagement of affected individuals within the healthcare system.[8,9] The Committee on Prevention and Control of STIs in the United States encourages a new approach, centered around understanding that sexual health is a "state of physical, emotional, mental, and social well-being in relation to sexuality; it is not merely the absence of disease, dysfunction or infirmity," as stated by World Health Organization (WHO).[10] Efforts should be more holistic, addressing principal drivers of health inequities, such as social determinants of health and structural bias and acknowledging how social networks and prevalence variations impact STI risk. To expand the STI workforce, the Centers for Disease Control and Prevention (CDC) encourages primary care providers help close STI screening and treatment gaps.[9,11]

Other than complete abstinence, the most effective way to prevent STI transmission is by maintaining a mutually monogamous sexual relationship between uninfected partners. Short of this, use of barrier contraceptive methods provide varying degrees of protection. Reducing the number of partners and increased testing can also lower risk. Obtaining a relevant and culturally sensitive sexual history is important to perform an accurate risk assessment. Even when providers ask about sexual and STI history, less often are number or gender of sex partners, or types of sexual practices collected. Patient interviews should include the five Ps: partners, practices, protection, past STIs, and prevention of pregnancy strategies.[11]

Treating STIs appropriately and early is important to curb transmission and prevent complications. Ensuring screening and/or treatment of sex partners is a critical facet of STI management. Partner referral can be initiated by the index patient or provider.[12] Expedited partner therapy (EPT) is another option when partners cannot receive a medical evaluation. In EPT, a partner's prescription is provided to the index patient for the dual benefit of treating the partner(s) and preventing reinfection of the index patient. Although legal status of EPT has not always been explicitly clear, the CDC and the Center for Law and the Public's Health have found that EPT is permissible or potentially allowable in all states and other US territories. Increased awareness and education are needed to remove barriers that continue to limit this practice.[12]

With the exception of human immunodeficiency virus (HIV) infection, reviewed in detail in Chapter 148, the most frequently occurring STIs in the United States are discussed in this chapter. The varied spectrum of clinical syndromes produced by common STIs is determined not only by the etiologic pathogen(s) but also by differences in anatomy and reproductive physiology. For many STIs, signs and symptoms overlap sufficiently to prevent accurate diagnosis without microbiologic confirmation. Frequently, symptoms are minimal or absent despite the presence of infection. Table 140-3 lists common clinical syndromes associated with STIs.[4]

TABLE 140-3

Selected Syndromes Associated with Common Sexually Transmitted Pathogens

Syndrome	Commonly Implicated Pathogens	Common Clinical Manifestations[a]
Urethritis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae*, *Trichomonas vaginalis*, *Ureaplasma, Mycoplasma genitalium*	Urethral discharge, dysuria
Epididymitis	*C. trachomatis*, *N. gonorrhoeae,* Enterobacterales	Scrotal pain, inguinal pain, flank pain, urethral discharge
Cervicitis/vulvovaginitis	*C. trachomatis, Gardnerella vaginalis*, herpes simplex virus, human papillomavirus, *N. gonorrhoeae, T. vaginalis*	Abnormal vaginal discharge, vulvar itching/irritation, dysuria, dyspareunia
Genital ulcers (painful)	*Haemophilus ducreyi*, herpes simplex virus	Usually multiple vesicular/pustular (herpes) or papular/pustular (*H. ducreyi*) lesions that can coalesce; painful, tender lymphadenopathy[b]
Genital ulcers (painless)	*Treponema pallidum*	Usually single papular lesion, usually painless
Genital/anal warts	Human papillomavirus	Multiple lesions ranging in size from small papular warts to large exophytic condylomas
Pharyngitis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae*	Symptoms of acute pharyngitis, cervical lymphadenopathy, fever[c]
Proctitis	*C. trachomatis*, herpes simplex virus, *N. gonorrhoeae, T. pallidum*	Constipation, anorectal discomfort, tenesmus, mucopurulent rectal discharge
Salpingitis	*C. trachomatis, N. gonorrhoeae*	Lower abdominal pain, purulent cervical or vaginal discharge, adnexal swelling, fever[d]

[a] For some syndromes, clinical manifestations can be minimal or absent.

[b] Recurrent herpes infection can manifest as a single lesion.

[c] Most cases of pharyngeal gonococcal infection are asymptomatic.

[d] Salpingitis increases the risk of subsequent ectopic pregnancy and infertility.

First, STIs commonly presenting with urethritis or vaginal discharge and associated complications are discussed, followed by STIs commonly associated with genital ulcers or lesions. Several STIs not included in this chapter warrant mention, including increased awareness of proctitis among MSM caused by Gram-negative bacteria normally present in the microbiota, such as *Campylobacter* and *Shigella* species, as well as atypical organisms, such as herpes simplex virus (HSV). Outbreak concerns and growing viral hepatitis rates led to updates in screening recommendations. The most current information on the epidemiology, diagnosis, and treatment of these and other STIs can be obtained at the CDC Website (http://www.cdc.gov).

GONORRHEA

Epidemiology and Etiology

Gonorrhea is the second most commonly reported notifiable disease in the United States.[1,4] Since the mid-1990s through early 2000s, rates of reported cases in the United States remained relatively stable. However, since a historic low in 2009, rates of gonorrhea have increased 92% with 616,392 cases reported to the CDC in 2019 equating to 188.4 cases/100,000 persons compared to 98.1 cases/100,000 persons in 2009.[1] Of growing concern are substantial numbers of infections that remain undiagnosed and unreported, thereby perpetuating spread of disease. Reported cases among males increased 112% compared to 42% among females from 2012 to 2019. Higher rates in males may be representative of increased transmission, detection via extra-genital screening among MSM, or both.[1]

In 2013, the CDC identified drug-resistant *N. gonorrhoeae* as a top three pathogen presenting an urgent level threat, posing an immediate health threat requiring urgent and aggressive action.[13] The 2019 update maintains the urgent threat level, showcasing increasing resistance over time and doubling of infections from 2013 to 2019.[14] Additionally, the WHO identified drug-resistant *N. gonorrhoeae* as high priority for new antibiotic.[15] Due to rising resistance, large numbers of asymptomatic infections, and ease of transmission, gonorrhea is difficult to control. Additionally, HIV infection is more easily transmitted in patients coinfected with gonorrhea.[4]

Pathophysiology

N. gonorrhoeae, the causative agent of gonorrhea infections, a Gram-negative diplococcus, does not have any animal or environmental reservoirs and humans are the only known host. *N. gonorrhoeae* infects mucosa of the urethra, endocervix, anorectum, pharynx, and conjunctiva. After mucosal damage is established, polymorphonuclear (PMN) leukocytes invade tissue, form submucosal abscesses, and resulting in purulent exudates.[4,16]

Gonorrhea is highly transmissible via sexual contact. Female risk of acquisition after a single episode of vaginal intercourse with an infected male partner is 50% to 70%; however, risk of female-to-male transmission following a single act is 20%.[17,18] With repeated exposure, risk of female-to-male transmission increases to 60% to 80%.[17] Although transmission rates for other types of sexual contact are not quantified, anal intercourse is likely more efficient while oral sex is less efficient than penile-vaginal sex.[16]

Clinical Presentation

Individuals infected with gonorrhea can be symptomatic or asymptomatic and have infections involving several anatomic sites. Interestingly, most of untreated symptomatic patients become asymptomatic within 6 months, with only a few becoming asymptomatic carriers of disease.[4,16] In settings where sexually active women are routinely screened for subclinical infections, most diagnosed with gonorrhea are asymptomatic. Up to 50% of women experience nonspecific symptoms, including mucopurulent vaginal discharge or post-intercourse vaginal bleeding. In comparison, 90% of males experience symptoms within 2 to 6 days following exposure, most commonly mucopurulent penile discharge or dysuria.[1,19] The most common clinical features of gonococcal infections are presented in Table 140-4.

TABLE 140-4

Presentation of Gonorrhea Infections

	Males	Females
General	Incubation period: 1-14 days	Incubation period: 1-14 days
	Symptom onset in 2-8 days	Symptom onset in 10 days
Site of infection	Most common: urethra	Most common: endocervical canal
	Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Commonly symptomatic, may be asymptomatic	Can be asymptomatic or minimally symptomatic
	Urethral infection: dysuria and urinary frequency	Endocervical infection: usually asymptomatic or mildly symptomatic
	Anorectal infection: asymptomatic to severe rectal pain	Urethral infection: dysuria, urinary frequency
	Pharyngeal infection: asymptomatic to mild pharyngitis	Anorectal and pharyngeal infection; symptoms same as for men
Signs	Purulent urethral or rectal discharge can be scant to profuse Anorectal: pruritus, mucopurulent discharge, bleeding	Abnormal vaginal discharge or uterine bleeding; purulent urethral or rectal discharge can be scant to profuse
Complications	Rare (epididymitis, prostatitis, inguinal lymphadenopathy, urethral stricture)	PID and associated complications (ie, ectopic pregnancy, infertility)
	Disseminated gonorrhea	Disseminated gonorrhea

Complications associated with untreated gonorrhea appear more pronounced in women, likely a result of a high percentage who experience nonspecific or minimal symptoms. As a result, many women do not seek treatment until after development of serious complications, such as pelvic inflammatory disease (PID). Approximately 10% to 20% of women with gonorrhea develop PID.[1,6,20] Left untreated, PID can cause infertility and ectopic pregnancies. Previous reports indicate 0.5% to 3% of gonorrhea infections result in disseminated gonococcal infection (DGI), but the risk may be less given declining prevalence of strains prone to dissemination.[21–23] Usual clinical manifestations of DGI are tender necrotic skin lesions, tenosynovitis, and monoarticular arthritis, or rarely meningitis or endocarditis.[4,16]

Diagnosis

Obtaining specific microbiologic diagnosis is recommended to reduce complications, reinfections, and transmission versus clinical diagnosis. Diagnosis of gonococcal infections can be made by Gram-stained smears, culture, or detection of cellular components (eg, enzymes, antigens, or DNA).[4]

Nucleic acid detection tests replaced culture or Gram stain in most settings as the primary diagnostic or screening test. These offer increased sensitivity and/or specificity over traditional diagnostic methods and provide more rapid results versus culture.[4,24]

Nucleic acid amplification tests (NAATs) are the most widely used and employ techniques and have high sensitivity for detecting *N. gonorrhoeae* using noninvasive specimens (eg, self-collected urine specimens, vaginal swabs). A NAAT is recommended by the CDC for detection of gonorrhea[4,24] and are approved for endocervical (women), urethral (men), and urine specimens. Extragenital diagnostic NAAT testing is now available for pharyngeal and rectal samples, in combination with testing for *Chlamydia trachomatis*.[25] A major drawback of NAATs is their inability to provide resistance data. In cases of documented treatment failure, culture and antimicrobial susceptibility testing is recommended.[4,24]

While NAATs are most commonly used in clinical practice, Gram stains can be used to make a presumptive diagnosis of gonorrhea infections. A Gram stain performed on purulent male urethral discharge is diagnostic for infection when Gram-negative diplococci are identified within PMN leukocytes. However, due to lower sensitivity, Gram-stained smears are not recommended for diagnosis of endocervical, rectal, pharyngeal, and asymptomatic male urethral infections. Because of the pharyngeal presence of nonpathogenic *Neisseria* spp., Gram stain is not useful in pharyngeal infection diagnosis.[4,16]

Bacterial cultures are highly sensitive and specific, provide opportunity for susceptibility testing, and can be performed on a variety of specimens. Prolonged turnaround times, decreased sensitivity compared to NAATS, and additional laboratory requirements preclude widespread usage. With the expansion of FDA-approval of NAATs on various specimen types, culture is primarily reserved for cases of suspected or documented treatment failures, as a test of cure (TOC) following use of alternative treatment regimens, or when evaluating for DGI.[4]

Routine screening for *N. gonorrhoeae* is recommended in certain populations to reduce burden of disease and morbidity associated with gonococcal infection. As females are more commonly asymptomatic, the CDC and US Preventative Services Task Force (USPSTF) recommend routine annual screening for gonococcal infection for all sexually active women younger than 25.[4,26] For those 25 years and older, annual screening is recommended for those at increased risk of gonococcal infection (eg, multiple or new sexual partners, partners with an STI, inconsistent condom use, transactional sex, or history of STI[s]). Pregnant women should be screened for gonorrhea at the first prenatal visit and again during the third trimester, for those at continued risk. The CDC also recommends that MSM should be screened at least annually, regardless of condom use, testing sites involved with sexual activity.[4]

Treatment

① *N. gonorrhoeae* has developed resistance to all antibiotics previously used for treatment, including sulfonamides, penicillins, tetracyclines, fluoroquinolones, and early generation macrolides and cephalosporins. In 2020, the CDC issued updated gonorrhea treatment recommendations.[27]

A single-500mg ceftriaxone dose is recommended for treatment of uncomplicated gonococcal infections. Previously, dual antibiotic therapy with different mechanisms of action (ceftriaxone plus azithromycin or doxycycline) was recommended to delay further development of cephalosporin resistance. However, rising incidence of azithromycin resistance, antimicrobial stewardship concerns regarding potential microbiome harm, pharmacokinetic and pharmacodynamic considerations, and continued low ceftriaxone resistance, influenced the changed recommendation to current single-drug regimen. Single-dose intramuscular (IM) ceftriaxone remains the only recommended agent for treating gonorrhea as ceftriaxone-based regimens have well-documented efficacy in the treatment of urethral, cervical, rectal, and pharyngeal infections.[4,27,28] (Table 140-1). To optimize pharmacokinetic and pharmacodynamic properties of ceftriaxone, the dose of ceftriaxone was increased from previous recommendations. Additionally, patients weighing 150 kg or more should receive ceftriaxone 1 g.[4]

An 800-mg oral dose of cefixime may be substituted if ceftriaxone is unavailable or not feasible, but due to reduced bactericidal levels and efficacy, especially in pharyngeal infections, this regimen is not preferred. Note that based on pharmacokinetic and pharmacodynamic properties, the dose of cefixime was optimized to 800 mg compared to the previous dose of 400 mg.[4,27] Additionally, only ceftriaxone is effective in treating pharyngeal gonorrhea as oral cephalosporins do not reliably cure these infections.[27,28]

Because coexisting chlamydial infections are common, documented in up to 50% of women and 20% of men with gonorrhea, and the symptoms may be similar to that of gonorrhea, for those where concurrent chlamydial infection has not been ruled out, chlamydia treatment should be added.[27,29] Doxycycline 100 mg orally twice daily for 7 days is preferred to azithromycin 1 g orally as a single dose.[27] Where previously azithromycin and doxycycline were both considered first-line therapy, this change was based on data suggesting lower efficacy rates when treating chlamydial with azithromycin compared to doxycycline, with increased concern regarding rectal chlamydia.[30–32]

Despite resistance concerns, to date, ceftriaxone treatment failure in the United States has not been reported. If cephalosporins cannot be used, due to allergy or concern for resistance, the recommended alternate regimen is a single-dose of 240-mg IM gentamicin in combination with 2-g oral azithromycin. While azithromycin (2 g) as a single dose appears highly effective in eradicating both gonorrhea and chlamydia, it is not recommended as a preferred alternative due to concerns regarding resistance. GI side effects are common with the 2-g dose of azithromycin.[27,33]

Parenteral ceftriaxone is the recommended therapy for DGI, including meningitis and endocarditis, and any type of gonococcal infection in children. In DGI, patients should be hospitalized and treated with ceftriaxone or an alternative parenteral cephalosporin (see Table 140-1). Although marked improvement is usually noted within 48 hours of initiating therapy, treatment should be continued for at least 7 days, with longer durations necessary for serious infections, such as meningitis and endocarditis.[4] Gonococcal ophthalmia is highly contagious in adults and neonates and requires ceftriaxone therapy. Single, but higher, dose therapy is adequate for gonococcal conjunctivitis, although some physicians recommend continuing therapy until cultures are negative at 48 to 72 hours. Topical antibiotics are not effective when used alone for ocular infections and are unnecessary with appropriate systemic therapy. Infants with any evidence of ocular infection should be evaluated for signs of DGI.[4,34]

Treatment of gonorrhea during pregnancy is essential to prevent ophthalmia neonatorum. Pregnant women infected with *N. gonorrhoeae* should be treated with a single intramuscular dose of ceftriaxone 500 mg, with the addition of 1 g of oral azithromycin if chlamydia has not been ruled out. Fluoroquinolones and tetracyclines are contraindicated in pregnancy. Gonococcal infection in newborns results primarily from passage through an infected birth canal, but may be transmitted in utero. Conjunctival involvement, characterized by intense, bilateral conjunctival inflammation with chemosis, usually develops within 7 days of delivery. If not treated promptly, corneal ulceration and blindness can develop. Because the law in most states requires neonatal prophylaxis with topical ocular antimicrobials, gonococcal ophthalmia neonatorum is rare in the United States. The CDC recommends erythromycin (0.5%) ophthalmic ointment be instilled in each conjunctival sac immediately postpartum.[4,27,34]

Patient Care Process for Genital Infection due to *Neisseria gonorrhoeae*

Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document

Collect

- Patient characteristics (eg, age, gender, pregnancy status)
- Patient medical history (personal and family)
- Social history, including sexual history
- Current medications
- Objective data
    - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight
    - Laboratory data including urine NAATs for gonorrhea and chlamydia, and/or urethral or vaginal cultures
    - Signs and symptoms consistent with gonorrhea (dysuria, mucopurulent urethral or vagina discharge)

Assess

- Presence of additional STIs (chlamydia, syphilis, HIV, etc.)
- Presence of extra-genital infection
- Ability/willingness to obtain follow-up testing as needed
- Ability/willingness to notify sexual partners
- Emotional status (eg, presence of anxiety, depression)

Plan

- Drug therapy regimen including, dose, route, frequency, and duration (Table 140-1)
- Monitoring parameters including efficacy (eg, retest 3 months after treatment) and safety, frequency and timing of follow-up
- Patient education (eg, purpose of treatment, notification of sexual partners, safe sexual practices, drug-specific information)
- Self-monitoring for resolution of gonorrhea symptoms, and seeking follow-up for a reevaluation if not resolved
- Referrals to other providers when appropriate (eg, HIV care, behavioral health)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (eg, retest 3 months after treatment)
- Offer expedited partner therapy for patient’s sexual partner(s) and partner education

Follow-up: Monitor and Evaluate

- Resolution of symptoms (eg, dysuria, mucopurulent urinary or vaginal discharge); in absence of symptom resolution after treatment, assess for resistance by obtaining culture and susceptibilities Presence of adverse effects (eg, rash or gastrointestinal [GI] upset)
- Patient adherence to treatment plan
- Reevaluation of laboratory tests in specific time frames (eg, retest after 3 months for retest)

**Collaborate with patient, caregivers, and other healthcare professionals.*

TABLE 140-1

Treatment of Gonorrhea

Type of Infection	Recommended Regimens[a]	Alternative Regimens[a]
Uncomplicated infections of the cervix, urethra, and rectum in adults	Ceftriaxone 500 mg IM once[b,c]	Gentamicin 240 mg IM[d] *plus* Azithromycin 2 g orally once *or* When ceftriaxone administration is not feasible, Cefixime 800 mg orally once[c]
Uncomplicated infections of the pharynx	Ceftriaxone 500 mg IM once[b,c]	Consult with infectious disease expert
DGI in adults (>45 kg)	Ceftriaxone 1-2 g IM or IV every 12-24 hours[c,e]	Cefotaxime 1 g IV every 8 hours[c,e] or ceftizoxime 1 g IV every 8 hours[c,e]
Gonococcal conjunctivitis in adults	Ceftriaxone 1 g IM once[f]	
Ophthalmia neonatorum	Ceftriaxone 25-50 mg/kg IV or IM once (not to exceed 250 mg)	
Infants born to mothers with gonococcal infection (prophylaxis)	Erythromycin (0.5%) ophthalmic ointment in a single application[g] Ceftriaxone 25-50 mg/kg IM or IV once (not to exceed 125 mg)	

[a] Recommendations are those of the CDC.

[b] For patients weighing > 150 kg, a 1-g dose of ceftriaxone is recommended.

[c] If chlamydial infection cannot be ruled out, treatment for chlamydia should be administered. Preferred therapy is doxycycline 100 mg orally twice daily × 7 days. Azithromycin 1 g orally once may be used as an alternative. Tetracyclines are contraindicated during pregnancy. Pregnant women should be treated with recommended cephalosporin-based combination therapy. In severe cephalosporin allergy, consultation with an infectious diseases expert is recommended.

[d] For patients with severe cephalosporin allergy.

[e] Parenteral treatment duration should be determined in consultation with an infectious diseases expert. Gonococcal meningitis should be treated with ceftriaxone 2g IV every 12 hours. Parenteral therapy for meningitis should be continued for at least 10 to 14 days and at least 4 weeks in endocarditis.

[f] A single lavage of the infected eye with normal saline should be considered; empiric therapy for *C. trachomatis* is recommended.

[g] Efficacy in preventing chlamydial ophthalmia is unclear.

Evaluation of Therapeutic Outcomes

Persistent symptoms following treatment with a recommended regimen often indicate reinfection rather than treatment failure, reflecting the need for improved patient education and sex partner referral. If reinfection is most likely, retreatment with the initial regimen is recommended. However, reinfection can no longer be assumed due to increased rates of drug resistance and subsequent treatment failure. True treatment failure should be considered in persons whose symptoms do not resolve within 3 to 5 days after appropriate treatment or who failed a TOC (positive culture 72 hours after or positive NAAT at least 7 days after receiving treatment) and abstained from sexual contact during the posttreatment 7-day follow-up period. The CDC recommends all treatment failures receive culture and sensitivity testing. Persistent symptoms may also be due to other infectious causes, such as *C. trachomatis*.[4,16,27]

While the CDC does not recommend a TOC for patients with uncomplicated urogenital or rectal gonorrhea treated, any patient treated for pharyngeal gonorrhea should return 7 to 14 days after treatment for a TOC. The TOC test may be either culture or NAAT; however, if the NAAT is positive, confirmatory culture should be obtained prior to retreatment. Antimicrobial susceptibilities should be obtained for all TOC positive cultures. Patients who require retreatment should receive TOC 7 to 14 days following the second regimen. Additionally, as reinfection within 12 months occurs in 7% to 12% of persons treated for gonorrhea, all patients who receive treatment for gonorrhea should be retested 3 months after treatment or when the patient next presents for medical care in the following 12 months.[4,35,36]

Recent sex partners (within 60 days of preceding onset of symptoms or diagnosis) should be referred for evaluation and treatment. The recommended EPT regimen for uncomplicated gonorrhea infections is a single oral dose of cefixime 800 mg, with the addition of oral doxycycline 100 mg twice daily for 7 days if chlamydia cannot be ruled out.[27] Patients and sex partners should abstain from unprotected sexual intercourse for 7 days after both have completed treatment and symptoms have resolved.[4] EPT is contraindicated for females experiencing signs or symptoms of PID and should seek prompt medical care. EPT should be used with caution among MSM due to high rates of co-infection of HIV and syphilis, and inadequate data regarding the EPT efficacy due to concerns of cefixime resistance rates in this population.

CHLAMYDIA TRACHOMATIS

Epidemiology and Etiology

Over 1.8 million cases of chlamydia infection were reported in 2019, making it the most frequently reported notifiable condition in the United States since 1994.[1] Since 2000, chlamydia has been a notifiable condition in all 50 states and infection rates have continued to rise. However, due to the silent nature of many infections, more than double the number of cases reported occur annually.[1,2] Left untreated, chlamydia infections can cause PID, infertility, ectopic pregnancy, and chronic pelvic pain.[4,37]

Chlamydia is more commonly reported in females, approximately 1.75 times the rate in males, reflective of increased screened. Rates among men have increased 32% from 2015 to 2019 and may be reflective of the increased number of male testing with increased urine and extragenital screening, increased transmission among MSM, or both.[1] Chlamydia is also a primary cause of nongonococcal urethritis (NGU), accounting for up to 40% of cases.[4,38,39]

Coinfection with chlamydia occurs in a substantial number of individuals with gonorrhea and all individuals diagnosed with *N. gonorrhoeae* should be assumed to have *C. trachomatis* present, until chlamydial infection has been ruled out.[4] Chlamydial infections, especially rectal infections, are associated with significantly increased risk of acquiring HIV infection.[40] In addition to genital infections, ocular infections in adults (via autoinoculation) and infants (via vaginal delivery through an infected birth canal) are reported. Pharyngeal and rectal infections may develop secondary to orogenital or receptive anal intercourse, respectively, with an infected individual.[4,37]

Pathophysiology

C. trachomatis is an obligate intracellular bacterium that exclusively infects humans, via infection of mucosal epithelial cells. Like viruses, chlamydiae require cellular material from host cells for replication and eventually lead to host cell death. *C. trachomatis* shares a similar outer membrane and ribosomes to Gram-negative bacteria, but lacks cell-wall peptidoglycan, and cannot be detected via Gram staining. Their complex two-stage lifecycle includes an infectious and noninfectious forms, and even after treatment nonviable and noninfectious organisms may persist within cells for up to 3 weeks.[37]

Risk of chlamydia transmission after exposure is not well described, but is believed to be less than that of *N. gonorrhoeae*. The risk of male-to-female and female-to-male transmission is 39% and 32%, respectively.[41] The rate of transmission per-act is 10%, increasing to 55% with multiple encounters between sexual partners.[42]

Clinical Presentation

Chlamydia causes a range of clinical syndromes, including urethritis, cervicitis, proctitis, and conjunctivitis. In comparison with gonorrhea, chlamydial genital tract infections are more frequently asymptomatic, and when present, symptoms tend to be less noticeable. Urethral discharge is usually less profuse and more mucoid or watery than that associated with gonorrhea.[4,37,38] Many cases of chlamydia in asymptomatic or minimally symptomatic women are diagnosed as a result of screening. Table 140-5 summarizes usual clinical presentations of chlamydial infections.

TABLE 140-5

Presentation of Chlamydia Infections

	Males	**Females**
General	Incubation period: 35 days Symptom onset: 7-21 days	Incubation period: 7-35 days Usual symptom onset: 7-21 days
Site of infection	Most common: urethra Others: rectum (receptive anal intercourse), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	More than 50% of urethral and rectal infections are asymptomatic Urethral infection: mild dysuria, discharge Pharyngeal infection: asymptomatic to mild pharyngitis	More than 66% of cervical infections are asymptomatic. Urethral infection: usually subclinical; dysuria and frequency uncommon Rectal and pharyngeal infection: symptoms same as for men
Signs	Scant to profuse, mucoid to purulent urethral or rectal discharge Rectal infection: pain, discharge, bleeding	Abnormal vaginal discharge or uterine bleeding, purulent urethral or rectal discharge can be scant to profuse.
Complications	Epididymitis, Reiter's syndrome (rare)	PID and associated complications (ie, ectopic pregnancy, infertility) Reiter's syndrome (rare)

Chlamydia can be transmitted to an infant during contact with infected cervicovaginal secretions. Nearly two-thirds of infants acquire chlamydial infection after endocervical exposure, with primary morbidity associated with seeding of the infant's eyes, nasopharynx, rectum, or vagina. In exposed infants, neonatal conjunctivitis develops in as many as 50%, and pneumonia develops in up to 16%. Inclusion conjunctivitis in newborns is usually self-limited, but can result in scarring and micropannus of the cornea. Interstitial pneumonitis occurring secondary to carriage in the nasopharynx typically is mild, but it can be severe and require hospitalization.[4,37,43]

Diagnosis

③ Laboratory confirmation of chlamydial infection is important because of the relative lack of symptom specificity when present.[4] Cell culture is the reference standard against which all other diagnostic tests are measured. Because chlamydiae are obligate intracellular organisms, specimens for culture must be obtained from endocervical (women) or urethral (men) epithelial cell scrapings rather than from urine or urethral discharges. Although tissue culture techniques have close to 100% specificity, the sensitivity is as low as 70%. Because of the technical demands of specimen collection, transport, processing, expense, and prolonged time until results (3-7 days), culture is not widely used for diagnostic purposes. However, culture remains the diagnostic standard in medicolegal cases, such as sexual assault and child abuse because of its high specificity and ability to detect only viable organisms.[4,37]

Similar to gonorrheal testing, NAATs can be used to detect small amounts of chlamydial DNA or RNA, and are highly sensitive and specific for detecting infection in urine, urogenital, and anal specimens. As such, they are recommended for detecting chlamydia infection.[4] In 2019, NAATs were approved for diagnosis of chlamydial infection in extragenital sites including the pharynx and rectum.[26] Use of self-collected vaginal or anal specimens or first-void urine samples offers greater patient acceptability. Because NAATs can detect as little as a single-gene copy in a specimen, whether it is live or a nonviable organism, nucleic acid residues that persist following successful antibiotic therapy can result in a false-positive test for several weeks following cure. Molecular tests that do not use nucleic amplification are no longer recommended for diagnosis of *C. trachomatis* because of their poor sensitivity in comparison to NAATs.[4,25]

Because of the high rate of asymptomatic disease and the high prevalence of chlamydial infection in sexually active females 25 years of age or younger and sexually active women with new sex partners or multiple sex partners, the CDC and USPSTF recommends routine annual screening in these individuals.[4,27] Additionally, the CDC recommends routine, at least annual, chlamydia screening of genital and rectal sites in MSM populations. Screening for rectal chlamydia among MSMs may also be a cost-effective intervention for HIV prevention.[44] Pregnant women are recommended to be screened at the first prenatal visit and during the third trimester if at continued risk.[4]

Treatment

Many antimicrobials, including tetracyclines, macrolides, and some fluoroquinolones, display good *in vitro* and *in vivo* activity against *C. trachomatis*. In most clinical trials, cure rates exceed 90% for these agents.[4,36,37] Treatment of *C. trachomatis* is limited based on the organism's unique life cycle. Antibiotics must target the intracellular active form, requiring medications with good intracellular penetration. Additionally, to maintain concentrations throughout the organisms life-cycle (up to 48 hours), selection of an antibiotic with long half-life or prolonged course of therapy is important.

Previously, single-dose azithromycin 1 g orally or doxycycline 100 mg orally twice daily for 7 days were equally considered regimens of choice for treatment of uncomplicated urogenital chlamydia infections (Table 140-6).[4] Because of its prolonged serum and tissue half-life, azithromycin is the only single-dose therapy effective in treating *C. trachomatis*. Both therapies clear over 97% of urogenital infections; however, there are concerns regarding azithromycin efficacy in rectal chlamydia.[30–32,45–47] As rectal chlamydia may occur by autoinoculation from the vaginal tract and cannot be predicted by sexual activity, doxycycline is now preferred as first line. Additionally, doxycycline demonstrates better *in vitro* activity against *C. trachomatis*.[48] For those patients with adherence concerns, azithromycin may be used, but TOC after treatment is recommended. Although some fluoroquinolones have activity against *C. trachomatis*, high dosages have not consistently eradicated chlamydial infections.[4,37,38]

TABLE 140-6

Treatment of Chlamydia Infections

Infection	Recommended Regimens[a]	Alternative Regimens
Uncomplicated urethral, endocervical, or rectal infection in adults	Doxycycline 100 mg orally twice daily for 7 days	Azithromycin 1 g orally once[b], *or* levofloxacin 500 mg orally once daily for 7 days
Urogenital infections during pregnancy	Azithromycin 1 g orally as a single dose	Amoxicillin 500 mg orally three times daily for 7 days
Conjunctivitis of the newborn or pneumonia in infants	Erythromycin base or ethylsuccinate 50 mg/kg/day orally in four divided doses for 14 days[c,d]	Azithromycin suspension 20 mg/kg/day orally once daily for 3 days[c]

[a] Recommendations are those of the CDC.

[b] Azithromycin may be used if there are concerns for nonadherence. Test after treatment is recommended due to reduced efficacy in rectal chlamydia.

[c] An association between oral erythromycin and azithromycin and infantile hypertrophic pyloric stenosis (IHPS) has been reported in infants aged <6 weeks. Infants treated with either of these antimicrobials should be followed for signs and symptoms of IHPS.

[d] Topical therapy alone is inadequate for ophthalmia neonatorum and is unnecessary when systemic therapy is administered. Effectiveness of erythromycin treatment is approximately 80%; therefore, a second course of therapy may be required.

For pregnant women, treatment can significantly reduce the risk of pregnancy complications and newborn transmission. Because tetracyclines and fluoroquinolones are contraindicated during pregnancy, azithromycin is recommended (see Table 140-6). Due to concerns regarding persistence of chlamydia infections after exposure to penicillin-class antibiotics, amoxicillin is an alternative therapy only in pregnant women. When compliance with a multiday regimen is a concern, azithromycin is the preferred treatment in women, regardless of pregnancy status, and directly observed single-dose administration ensures adherence. TOC 3 to 4 weeks after completion should be obtained for pregnant patients treated for chlamydial infections.[4]

C. trachomatis transmission during perinatal exposure can result in neonatal or infant infections of the eye, oropharynx, lungs, urogenital tract, and rectum. Despite efficacy in preventing gonococcal ophthalmia, topical erythromycin ointment (0.5%) appears less effective in preventing chlamydial ophthalmia and has no effect on nasal carriage or colonization, so the potential for other infections, including pneumonia, remains. Because of high percentage of treatment failures, topical therapy is not recommended to treat ophthalmia caused by *C. trachomatis*. Instead, an oral erythromycin regimen is recommended.[4]

Evaluation of Therapeutic Outcomes

Treatment of chlamydial infections with recommended regimens is highly effective; therefore, posttreatment laboratory testing for therapeutic failure is not recommended unless symptoms persist or there are specific concerns (eg, regimen nonadherence or pregnancy). However, due to high risk of reinfection, all patients treated for chlamydia should be retested approximately 3 months after treatment. Posttreatment tests should not be performed for at least 3 weeks following completion of therapy due to false positives with continued presence of nonviable organisms.[4] When posttreatment tests are positive, suspect noncompliance, failure to treat sexual partners, or laboratory error rather than inadequate therapy or resistance. Infants with pneumonitis should receive follow-up testing, and sometimes subsequent courses of therapy, because erythromycin is only 80% effective.[4,37]

Sex partners of patients with *C. trachomatis* infections should be examined, tested for other STIs, and counseled on prevention. EPT may also be offered with either azithromycin or doxycycline-based regimens. Patients, and sex partners, should abstain from unprotected sexual intercourse for 7 days after both have completed treatment and symptoms have resolved.[4]

TRICHOMONIASIS

Epidemiology and Etiology

In 2018, 6.9 million people developed trichomoniasis in the United States, making it the most common nonviral STI. The prevalence is approximately 2.6 million, with 2.1% of US women aged 14 to 59 years infected at a given time.[2,5,49] The distribution of trichomoniasis is varied; women are six times more likely to be infected than men, with disproportionate infection among women 40 years of age or older (11%) and Black women (13%).[49] Men who have sex with women are at greater risk of trichomoniasis compared to MSM exclusively and are usually asymptomatic. The causative organism, *Trichomonas vaginalis*, is primarily transmitted through sexual contact although acquisition from inanimate objects is a theoretical possibility since the organism can survive for up to 3 hours in a wet environment.[50] Neonatal infections may also occur. Coinfection with other STIs is not unusual, and the inflammatory response produced by trichomoniasis increases the risk of acquiring HIV by at least 50%.[4,50–54]

Pathophysiology

Trichomonads typically infect the squamous epithelium of the genital tract. Extragenital sites are epidemiologically important because infection can persist and result in reinfection. After attachment to vaginal or urethral mucosa, trichomonads elicit an inflammatory response that manifests as discharge containing large numbers of PMNs.[50]

Clinical Presentation

Trichomonal infections are reported more commonly in women than in men. Most patients experience minimal or no symptoms, with untreated infections lasting years. The clinical presentation of trichomoniasis in males and females is presented in Table 140-7. Trichomoniasis is one of the principal infectious causes of vaginal discharge (in addition to bacterial vaginosis and vulvovaginal candidiasis). In both genders, trichomoniasis can manifest as urethral discharge and dysuria and should be considered in NGU. Rarely, *T. vaginalis* can lead to epididymitis, prostatitis, and/or infertility in men and PID in women. During pregnancy, it can cause preterm rupture of membrane, premature delivery, endometritis, and low-birth-weight neonates.[4,50]

TABLE 140-7

Presentation of Trichomonas Infections

	Males	Females
General	Incubation period: 3-28 days Organism can be detectable within 48 hours after exposure to infected partner	Incubation period: 3-28 days
Site of infection	Most common: urethra Others: rectum (usually caused by rectal intercourse in MSM), oropharynx, eye	Most common: endocervical canal Others: urethra, rectum (usually caused by perineal contamination), oropharynx, eye
Symptoms	Can be asymptomatic (more common in males than females) or minimally symptomatic Urethral discharge (clear to mucopurulent) Dysuria, pruritus	Can be asymptomatic or minimally symptomatic Scant to copious, typically malodorous vaginal discharge (50%-75%) and pruritus (worse during menses) Dysuria, dyspareunia (pain with sexual intercourse)
Signs	Urethral discharge	Vaginal discharge Vaginal pH 4.5-6 Inflammation/erythema of vulva, vagina, and/or cervix Urethritis
Complications	Epididymitis and chronic prostatitis (uncommon) Male infertility (decreased sperm motility and viability)	PID and associated complications (ie, ectopic pregnancy, infertility) Premature labor, premature rupture of membranes, and low-birth-weight neonates (neonatal infection risk is low) Cervical neoplasia

Diagnosis

Testing for *T. vaginalis* should be performed on all women presenting with vaginal discharge and at least annually in women with HIV. Screening may be considered in settings of high prevalence (eg, STI clinic, correctional facilities) and for persons at increased risk for infection (eg, recent STI diagnosis, multiple sexual partners, transactional sex). *T. vaginalis* produces nonspecific symptoms that may be indistinguishable from bacterial vaginosis, which can be concomitantly present. Because *T. vaginalis* requires a pH range of 4.9 to 7.5 for survival, a vaginal discharge pH of greater than 5 usually indicates the presence of either *T. vaginalis* or *Gardnerella vaginalis*, a common cause of bacterial vaginosis. The simplest means of diagnosis is a wet mount of vaginal discharge where *T. vaginalis* is visualized via bright-field microscopy. Trichomoniasis is confirmed if characteristic pear-shaped, flagellated, motile organisms are observed. This technique is still readily used given its relative convenience for experienced personnel and low cost. However, the wet mount is only 51% to 65% sensitive, with lower sensitivities in men and women with low-grade, subacute, or chronic infections. Culture was the gold standard for trichomoniasis and is highly specific; however, these tests are labor intensive, expensive, not widely available, and have a long turnaround.[4,50,52–54]

Newer diagnostic tests are now widely available, with the sensitivities approaching those of culture techniques. NAAT are FDA-approved for *T. vaginalis* detection in vaginal, endocervical or urine specimens in women and is three to five times more sensitive than wet mount microscopy (95%-100%). In men, urethral swab specimens may yield a higher sensitivity than urine.[50,55] Rapid point of care tests are also readily available, allowing for office-based testing. Sensitivity among these tests can vary and might be higher in symptomatic women.[4,52–55]

Treatment

5 Recommended and alternative treatment regimens for *T. vaginalis* include either metronidazole or tinidazole (Table 140-8).[4] Metronidazole 500 mg twice daily for 7 days was more effective than 2 g single-dose regimen.[56] Increasing the dose for either agent to 2 g once daily for 7 days cures persistent

infections. Adding topical metronidazole or tinidazole may improve efficacy during persistent infection. Tinidazole 2 g orally as a single-dose is an alternative for women. Single-dose therapy with 2 g of metronidazole or tinidazole are recommended for men with trichomoniasis. To achieve maximal cure rates and prevent relapse, simultaneous treatment of infected sexual partners for presumed infection is recommended.[4,52–54]

TABLE 140-8

Treatment of Trichomoniasis

Type	Recommended Regimens[a]	Alternative Regimens[d]
Symptomatic and asymptomatic infections	Women Metronidazole 500 mg orally twice daily for 7 days[a,b,c] Men Metronidazole 2 g orally in a single dose[b,c]	Tinidazole 2 g orally in a single dose[c]
Persistent or recurrent infections Treatment in pregnancy[e]	Metronidazole 500 mg orally twice daily for 7 days[c]	Metronidazole 2 g orally once daily for 7 days *or* Tinidazole 2 g orally once daily for 7 days

[a] Recommendations are those of the CDC.

[b] Randomized controlled trial comparing metronidazole 500 mg twice daily for 7 days and a single 2 g dose in women found fewer treatment failures in the 7-day regimen.

[c] Metronidazole labeling approved by the FDA does not include this regimen. Dosage regimens for treatment of trichomoniasis included in the product labeling are the single 2 g dose; 250 mg three times daily for 7 days; and 375 mg twice daily for 7 days. The 250-mg and 375-mg dosage regimens are currently not included in the CDC recommendations.

[d] For men, data is lacking for alternative treatment regimens and regimens for persistent infection. Consult an infectious diseases specialist.

[e] Symptomatic pregnant women can be treated with this regimen at any stage of pregnancy.

In patients who fail to respond to an initial course of metronidazole therapy, a second course of therapy with metronidazole 500 mg twice daily for 7 days is recommended. Infections refractory to a second course of treatment often respond to a 2 g daily 7-day regimen of either agent.[4,57] Tinidazole should be considered after failure to a 7-day metronidazole regimen given its longer half-life, greater serum concentrations, and a lower minimum lethal concentration demonstrated in 60% of *T. vaginalis* isolates compared to metronidazole.[58] The combination of oral and intravaginal administration improves cure rates in refractory cases. There are higher rates of resistance with metronidazole (4%-10%) versus tinidazole (1%); however, resistance testing is not routinely performed by most laboratories. In persistent cases, consultation with the CDC is recommended for treatment and resistance testing.[53,59]

Metronidazole is associated with a risk of a disulfiram-like reaction, although published data has not supported this claim. *In vitro* and animal data described a possible inhibition of aldehyde dehydrogenase and subsequent increase in acetaldehyde levels, which can cause facial flushing, nausea, vomiting, and other symptoms. Although there are considerable human data describing disulfiram-like reactions after concomitant metronidazole and alcohol use, these manifestations may be attributed directly to alcohol. Most controlled studies failed to find an association between metronidazole with alcohol use and disulfiram-like reactions.[60] The updated CDC guidelines do not link metronidazole use with the potential for a disulfiram-like reaction in those that consume alcohol concurrently.[4]

The CDC recommends testing all symptomatic pregnant women for *T. vaginalis*, regardless of pregnancy stage, and to consider treatment. Concerns regarding the use of metronidazole in pregnant women and breastfeeding have been raised. Some clinicians prefer to delay treatment in women in the first trimester; however, metronidazole is pregnancy category B and may be used for treatment in any trimester. Tinidazole is pregnancy category C and should be avoided. Both agents are secreted in breast milk, although metronidazole is indicated for use in neonates and infants. Metronidazole concentrations in breast milk were deemed compatible with breastfeeding when the mother was given 500 mg three times daily, while 2-g dose warrants a 12 to 24 hour breastfeeding pause. Careful monitoring of breastfed child is recommended with metronidazole treatment of the mother. Breastfeeding should be deferred for 72 hours after a 2-g dose of tinidazole.[4,52]

Evaluation of Therapeutic Outcomes

Retesting for *T. vaginalis* is recommended for all sexually active women within 3 months following initial treatment due to high rates of reinfection. If retesting with NAAT is clinically warranted without reexposure (eg, third trimester), the optimal timing to prevent a false-positive is 3 weeks. Concurrent treatment of all sex partners is critical to ensure relief of symptoms and prevent reinfection and transmission. When patients remain symptomatic, it is important to ensure patient adherence and to determine if reinfection has occurred. In these cases, a repeat course of therapy, including sexual partner(s) is indicated. In situations where reinfection can be excluded, a relative resistance to metronidazole or tinidazole should be assumed, and an alternative regimen prescribed. Culture and sensitivity are warranted for infections unresponsive to alternative regimens.[4]

ASSOCIATED COMPLICATIONS

Mycoplasma Genitalium

Of notable importance is *Mycoplasma genitalium* (*M. genitalium*) infection, a common cause of NGU. The CDC has identified *M. genitalium* infections as an emerging issue due to the increasing rates of resistance and lack of diagnostic assays.[4,19,61,62]

M. genitalium is a known colonizer of the genital tract in both males and females; however, it is an emerging cause of urogenital infections.[4,19,61,62] While *C. trachomatis* accounts for a majority of NGU cases, *M. genitalium* is the causative pathogen in up to 20% of NGU cases and 25% of nonchlamydial NGU. Rates are even higher in persistent or recurrent NGU, constituting approximately 30% of cases.[4] The relationship between *M. genitalium* and other male anogenital tract infections, like epididymitis or clinical proctitis, is not well defined. The pathogenic role is even less defined in women, as infections are commonly asymptomatic, but has been isolated in up to 30% of cervical infections. However, women infected with *M. genitalium* are at a 2 to 2.5-fold increased risk of cervicitis, PID, infertility, and preterm delivery.[61] Many infections go undiagnosed, but *M. genitalium* should be suspected in persistent or recurrent urethritis or proctitis and considered in persistent or recurrent cervicitis or PID.[4,19,61,62] There are no current recommendations for routine screening in asymptomatic individuals.

M. genitalium lacks a cell wall and is a slow growing, fastidious organism. It is not readily cultured in a laboratory and, when able to grow, may take up to 6 months to isolate. NAATs are the preferred method to detect *M. genitalium*.[19,63]

The 7-day doxycycline regimen, a primary treatment option for NGU is largely ineffective for treatment of *M. genitalium* urethritis, with a median cure rate of 31%.[4] A 1-g single-dose of azithromycin was significantly more effective than doxycycline, and has been the mainstay of therapy for *M. genitalium* infections.[4,19,61,62] Unfortunately, resistance to azithromycin is rapidly emerging, with 50% of all *M. genitalium* infections caused by organisms already resistant to azithromycin. The overuse of macrolides to treat respiratory tract infections, like community acquired pneumonia, may play a role in azithromycin resistance seen in *M. genitalium*. Moxifloxacin, 400 mg daily for 7, 14, or 21 days, has been successfully used to eradicate *M. genitalium* infections.[61,62] To optimize chance of treatment success, CDC STI guidelines recommend doxycycline 100 mg twice daily for 7 days followed by moxifloxacin 400 mg daily for 7 days.[4,64] Macrolide susceptibility testing is unavailable in the United States. If macrolide susceptibility is known, a regimen of doxycycline 100 mg twice daily for 7 days followed by azithromycin 1 g and then 500 mg daily for 3 days is an alternative option. For those with unknown or known macrolide resistance, the doxycycline-moxifloxacin regimen is preferred.

As with all STIs, patients are recommended to abstain from unprotected sexual activity until both partners have completed treatment and are asymptomatic. Additionally, patients and their sexual partners should be screened for other STIs and counseled on risk of transmission and consequences of untreated infections. If a patient's sexual partner is not tested, the same treatment may be offered to both.[62]

Pelvic Inflammatory Disease

PID is an inflammatory disorder of the upper female genital tract and can include any combination of endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis that may result in long-term reproductive damage, including infertility, ectopic pregnancy, and chronic pelvic pain. It is most often caused by ascending infection of the vagina and cervix, most commonly with STI pathogens. Microorganisms that colonize the vaginal canal may also play a role, including anaerobes or causes of bacterial vaginitis, as well as enteric Gram-negative rods. The microbiologic etiology of acute PID is not well known. Where gonorrhea or chlamydia were once thought to be the primary cause, <50% of women with acute PID test positive for one of these organisms. The role of *M. genitalium* is unclear, but testing was unavailable for this organism until recently and may be considered in persistent cases.[4,20]

Acute PID is difficult to diagnose as many patients may be asymptomatic or have subtle, nonspecific symptoms. PID is often diagnosed based on clinical findings and confirmed with more invasive testing. Delays in diagnosis and treatment likely contribute to inflammatory sequelae and long-term reproductive damage. The hallmark sign of PID is sudden onset pelvic and lower abdominal pain, notably after menses. Additional signs may include abnormal vaginal discharge, intermenstrual or postcoital bleeding, dyspareunia, and dysuria. All patients with suspected PID should undergo cervical or vaginal NAAT testing for gonorrhea or chlamydia. Vaginal fluid may also be evaluated for signs of bacterial vaginosis. Negative endocervical screening does not rule out upper reproductive tract infections, but positive results may help guide therapy.[4,20]

Treatment for PID is targeted toward empiric coverage for *N. gonorrhoeae* and *C. trachomatis* and anaerobic bacteria. Patients with suspected PID should be initiated on treatment with ceftriaxone 1 g IV daily (or cefotetan 2 g IV every 12 hours or cefoxitin 2 g IV every 6 hours) plus doxycycline 100 mg orally twice daily for 14 days and metronidazole 500 mg orally twice daily for 14 days.[65] The addition of metronidazole resulted in reduced pelvic pain and was associated with higher clinical improvement compared to ceftriaxone and doxycycline alone. This is an update from the previous guideline recommendations and aligns with current gonorrhea and chlamydia treatment recommendations.[4] Patients who require hospitalization for PID should be initiated on a parenteral regimen. Once the patient is clinically stable and can tolerate oral medications, they can be switched to oral formulations to complete two weeks of therapy. Ampicillin-sulbactam 3 g IV every 6 hours plus doxycycline can be used as an alternative. Clindamycin 900 mg IV every 8 hours plus gentamicin IV is another alternative treatment regimen, but provides suboptimal coverage for anaerobic organisms.[4,66,67]

Clinical improvement (defervescence, reduction in abdominal/pelvic pain) should occur within 3 days of initiation of therapy. Intrauterine contraceptive devices (IUD) have not been associated with PID, outside of the initial 3 months after insertion. If an IUD user is diagnosed with PID, the IUD does not need to be removed, but may be considered if the patient does not show clinical improvement within 72 hours.[4] All patients with confirmed gonorrheal or chlamydial PID should be retested 3 months after treatment. Recent sex partners should also be evaluated and presumptively treated for chlamydia and gonorrhea, regardless of the etiology of PID. EPT may be offered and partners should be instructed to abstain from sexual intercourse until both partners have been treated and symptoms have resolved. Approximately one-third of women report chronic pelvic pain after treatment and resolution of PID. Infertility may occur in up to 20% of patients and ectopic pregnancy in <1%.[68] Routine screening for gonorrhea and chlamydia as recommended by the USPSTF and CDC, and early recognition of symptoms may help reduce the burden of disease.[4,27]

SYPHILIS

Epidemiology and Etiology

Syphilis is a chronic bacterial infection that presents through various stages. Although nearly eradicated in 2000, cases of syphilis have increased 400% in the United States from 2000 to 2019, with an annual total of primary and secondary syphilis diagnoses of around 39,000. While the rise of newly diagnosed cases are primarily attributed to males, a majority of whom identify as MSM, a 179% increase was observed in women during the years 2015 to 2019.[1] This increase among women has been accompanied by a threefold rise in congenital syphilis during the same period.[69] In 2018, one-third of congenital syphilis cases in live-born infants were symptomatic, while 6% of maternal syphilis cases resulted in stillbirth.[69]

Rates of coinfection with HIV have remained high, particularly among MSM. Similar to other STIs, syphilis can increase the risk of acquiring HIV in exposed individuals. In addition, immunologic defects in HIV-infected individuals can produce an atypical serologic response to syphilis. In particular, the possibility of delayed seroreactivity, markedly elevated serologic titers, and increased false-positive results could complicate the diagnosis, as well as assessment of treatment efficacy in HIV-positive individuals infected with syphilis. As a result of this association, the CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.[4,70]

Pathophysiology

The causative organism is *Treponema pallidum* subspecies *pallidum*, a spirochete. The primary mode of transmission is through sexual contact, with the organism penetrating through intact mucous membrane or a break in the cornified epithelium. The spirochetes replicate locally, followed by widespread dissemination through the lymphatic and intravascular systems. Transmissibility varies based on the stage of the infection, with the highest rates early in the course of disease. *T. pallidum* can also cross the placenta during any time of the pregnancy and during any stage of infection. Despite the limited risk of transmission after the first few years, approximately one-third of those are untreated will develop further clinical manifestations and irreversible complications, such as neurological and cardiovascular complications.[70]

Clinical Presentation

The clinical presentation of syphilis is varied with progression through multiple stages possible in untreated or inadequately treated patients (Table 140-9).

TABLE 140-9

Presentation of Syphilis Infections

General	
Primary	Incubation period: 10-90 days (mean, 21 days)
Secondary	Develops 2-8 weeks after initial infection in untreated or inadequately treated individuals
Latent	Develops 4-10 weeks after secondary stage in untreated or inadequately treated individuals; risk of secondary stage relapse within the first year
Neurosyphilis	Neuroinvasion can occur at any stage (weeks to years)
Tertiary	Develops in approximately 28% of untreated or inadequately treated individuals 10-30 years after initial infection
Site of Infection	
Primary	Genital or external genitalia area (perineum, mouth, throat)
Secondary	Multisystem involvement secondary to hematogenous and lymphatic spread
Neurosyphilis	Meninges, cerebral vasculature, brain parenchyma, eyes, ears
Tertiary	CNS, heart, bones, and joints
Signs and Symptoms	
Primary	Single, painless, indurated lesion (chancre) that erodes, ulcerates, and eventually heals (typical); regional lymphadenopathy is common; multiple, painful, purulent and/or multiple lesions possible
Secondary	Pruritic or nonpruritic rash (may involve the palms and soles), mucocutaneous lesions, flu-like symptoms, lymphadenopathy
Latent	Asymptomatic
Neurosyphilis	Meningitis (headache, photophobia, stiff neck), general paresis, stroke, dementia, ocular (blindness, blurred vision, eye pain) and otic (deafness, imbalance) complications
Tertiary	Cardiovascular syphilis (aortitis or aortic insufficiency), gummatous lesions involving any organ or tissue

CNS, central nervous system.

Primary Syphilis

The primary stage, characterized by a chancre on cutaneous or mucocutaneous tissue exposed to the organism, is highly infectious. Lesions are usually painless, solitary and indurated, although they may be painful and/or present as multiple lesions. Regional lymphadenopathy may accompany the chancre. Syphilis should be considered with atypical presentations as lesions can mimic other infectious or noninfectious etiologies. As such, appropriate diagnostic testing is important. Chancres heal within 4 to 6 weeks, while lymphadenopathy may persist longer.[70–72]

Secondary Syphilis

Often referred to as the "great imitator" due to its florid and diverse differential diagnosis, the secondary stage of syphilis is characterized by a variety of mucocutaneous eruptions resulting from widespread hematogenous and lymphatic spread of *T. pallidum*. Skin lesions are often maculopapular and are usually nonpruritic, developing first on trunk and proximal arms and disseminating bilaterally. Secondary syphilis lesions typically involve the palms and soles, can present as mucous patches, and/or can have a wart-like appearance (condylomata lata). Patchy alopecia is another finding periodically seen.

Constitutional symptoms often accompany secondary syphilis, such as malaise, low-grade fever, pharyngitis, headache, anorexia, and generalized lymphadenopathy. Subclinical hepatitis, renal dysfunction, and neurologic findings may also be present. If untreated, secondary syphilis disappears spontaneously within 1 to 6 months.[70–72]

Latent Syphilis

Persons with an absence of mucocutaneous lesions or other evidence of disease are in a latency period, which can only be diagnosed with positive serologic tests for syphilis. Prior to the availability of effective treatment, 25% of those infected developed secondary syphilis relapses, 90% of which occurred within the first year.[73] These individuals are thus deemed potentially infectious during this early period. By CDC terminology for the latent infection, the first year after acquisition is designated as early latent (or non-primary, non-secondary) syphilis.[74] Those with asymptomatic infection established to be over 12 months from exposure, or when a duration cannot be determined, are classified as late latent syphilis (or late or unknown duration syphilis). If left untreated, syphilis can slowly produce an inflammatory reaction in virtually any organ in the body. Most patients with late syphilis will have no further sequelae. However, approximately 28% will develop further disease years after the initial infection.[70–72]

Neurosyphilis

Neurologic manifestations, including ocular and otic, may present at any stage of syphilis. Central nervous system (CNS) invasion by treponemes can lead to CSF abnormalities (eg, pleocytosis, elevated protein levels) in up to half of the individuals with early infections, with the majority being devoid of symptoms (asymptomatic neurosyphilis). Some patients will have meningeal symptoms (eg, headache, photophobia, stiff neck) present in early infection. Meningovascular (eg, stroke, seizures) or parenchymal (eg, dementia, aphasia) are other complications of neuroinvasion, which at times may overlap. The latter manifestations are more apt to occur years after infection, although strokes have been described early in disease. Ocular findings, especially uveitis, can be part of the neurological presentation. Hearing loss and/or vestibular dysfunction (eg, dizziness, vertigo) are rare, although syphilis should be considered for patients presenting with these complaints.[70,71]

Tertiary Syphilis

Non-neurologic manifestations of late syphilis include benign gumma formation and cardiovascular syphilis. Gummas, nonspecific granulomatous lesions, are the classic lesions of late syphilis and can infiltrate any organ or tissue. Gummas of critical organs, such as the heart or brain, can be fatal. Cardiovascular disease often manifests as aortic insufficiency, ascending aortic aneurysm or myocarditis. Treatment of all patients with latent syphilis is essential, as there is no way to predict which patients will experience disease progression.[70]

Congenital Syphilis

In pregnant women with syphilis, *T. pallidum* can cross the placenta at any time during pregnancy. The risk of fetal infection is greatest in pregnant women with primary and secondary syphilis and declines in pregnant women with late disease. Transmission of syphilis during pregnancy occurs primarily transplacentally and can result in fetal death, prematurity, or congenital syphilis. Symptoms vary based on onset, with early congenital manifestations appearing from 2 weeks to 2 years, and late syphilis symptoms appearing after two years throughout adolescence. Manifestations of early congenital syphilis resemble those of secondary syphilis, in addition to other findings, notably hemolytic anemia, hepatic dysfunction, intrauterine growth retardation, bone deformities, or nephrotic syndrome. Deformities of the nose (saddle nose) and lower extremities (anterior bowing) are examples of untreated late syphilis complications.[70,72]

Diagnosis

Syphilis is diagnosed through a combination of clinical and/or laboratory criteria and is stage-dependent. Techniques used to directly visualize *T. pallidum*, such as darkfield microscopy, are now only performed by select facilities (eg, STI specialty clinics). Polymerase chain reaction (PCR)–based tests are used by some institutions despite not being commercially available in the United States. Unlike other methods, PCR does not require specimens from fresh lesions or tissue samples. Real-time PCR can detect *T. pallidum* DNA when primary syphilis is highly suspected, even when darkfield microscopy is negative.[75] PCR is also useful for detection in other bodily fluids and tissues.[70,71]

Serologic tests are the mainstay in the diagnosis and are based on two distinct antibody responses elicited by syphilis. Tests are categorized as nontreponemal or treponemal based on the type of antibodies they detect. Nontreponemal tests identify immunoglobulin released by inflamed tissues and/or *T. pallidum* by forming immune complexes with the reagent. Rapid plasma reagin (RPR) card test is the most common nontreponemal test. The Venereal Disease Research Laboratory (VDRL) slide test, another nontreponemal test, is almost exclusively used for CSF specimens. A positive RPR test can indicate the presence of any stage of syphilis or congenital syphilis if taken at least 3 weeks after exposure. RPR tests are simple and inexpensive, but require manual manipulation and interpretation.[70]

Beyond their screening role, RPR tests help monitor syphilis progression, treatment success, and identify reinfection as they measure *T. pallidum* antibody titers. Higher titers (eg, 1:512) correlate with a greater spirochetal burden and stage of infection. In 1% to 2% of secondary syphilis cases, the high concentrations of antibodies prevent the antigen-antibody complex from forming, leading to a false-negative. This phenomenon is called the "prozone" effect. Titers generally decline by at least fourfold after effective treatment (eg, 1:64 → 1:16), with only 20% of individuals failing to serorevert to a nonreactive test. Thus, strategic sequential RPR tests are an integral part of syphilis management. Access to previous diagnosis and treatment history is often necessary to determine if reinfection has occurred.[4,70,71,75]

In diagnosing all stages of syphilis, treponemal tests are more sensitive and specific than nontreponemal tests. Cost has contributed to their role as confirmatory tests rather than screening tools. Treponemal tests detect antibodies specific against *T. pallidum* antigens, which persist throughout a person's lifetime after infection. This test cannot distinguish between a new or past infection, nor treatment status. They can identify syphilis 6 to 14 days after a chancre develops, earlier than RPR tests (10-15 days). For many years, the fluorescent treponemal antibody absorption (FTA-ABS) test or the *T. pallidum* particle agglutination assay (TPPA) were the most frequently used treponemal tests. However, enzyme-linked immunoassays (EIAs) and chemiluminescent immunoassays (CIAs) are increasingly utilized as these processes are cheaper and allow for automated testing and interpretation. Advances in point of care could further remove challenges for screening and diagnosing syphilis, especially in rural and resource-limited areas.[4,70,71,75]

The traditional algorithm for diagnosing syphilis involves an initial RPR test, followed by a treponemal test for confirmation if the RPR was reactive. For individuals with a previously treated infection, presenting with new clinical suspicion of syphilis (or being screened due to high risk of re-exposure), a new RPR test should be collected. RPR results should be compared to their last titer. A fourfold or greater increase would suggest reinfection.[4,70,72,76]

For many laboratories with high volumes and programs screening large numbers (eg, prenatal screening), a reverse sequence algorithm is now a viable option. This strategy uses a treponemal test for the initial screen, with a positive test reflexively followed by an RPR test. If there is discordance with the RPR test, a second treponemal test distinct from the initial product would resolve the discrepancy. The availability of EIAs/CIAs for high throughput at increasingly lower costs have made this algorithm more attractive economically and logistically. Products testing for multiple pathogens, such as a point of care dual syphilis and HIV-1 test, have been approved and are in development.

False-positive tests occur more commonly with non-treponemal tests than treponemal ones, and can cause anxiety, stigmatization and unnecessary treatment. Acute febrile illnesses, after immunizations, pregnancy, injection drug use, hepatitis C infection, HIV, and autoimmune disease (particularly lupus erythematosus) can induce these false-positives. Regardless of which test is used initially, confirmation with the other type is necessary for the diagnosis. If the nontreponemal test is negative after a positive treponemal test during a reverse algorithm screening, a second treponemal test based on a different antigen than the original test should be performed to adjudicate the results.[4,70,72,76]

Taking an accurate and careful history is important when considering a syphilis diagnosis, particularly when lesions are not present or missed early in disease. Missed identification of primary lesions delay diagnosis and may lead to uncertainty when patients present in later stages, particularly given the wide range of syphilis manifestations. In latent disease, early non-primary, non-secondary syphilis can be differentiated from late or unknown duration syphilis if within the past 12 months an individual: had a negative RPR result, recent primary or secondary syphilis without current symptoms, a sex partner diagnosed with primary or secondary syphilis or a fourfold increase in RPR titers from a previously treated infection.[4,70]

A lumbar puncture is recommended for those with neurologic findings at any stage. A confirmatory diagnosis in those with a reactive VDRL from a CSF specimen of a patient with consistent clinical picture. However, a probable diagnosis can be made if there are neurologic symptoms, a positive serum RPR test and CSF abnormalities. A lumbar puncture is not required for diagnosis of ocular and otic syphilis as it yields an unremarkable CSF result in 30% and 90% of ocular and otic syphilis, respectively. For tertiary syphilis, diagnosis requires a clinically compatible case with microbiologic identification or a positive treponemal test.[4,70]

Maternal and congenital screening recommendations vary by state, with most requiring testing at the first prenatal visit. Some states mandate testing at the third trimester and/or delivery, whereas others recommend testing only for women at increased risk (eg, recreational drug use, STI diagnosis during pregnancy, high prevalence areas, or partner(s) with HIV). Additional maternal risk factors include multiple partners (regardless of HIV status), engaging in transactional sex, late or no prenatal care, incarceration, and unstable housing or homelessness. A congenital syphilis diagnosis can be made if the mother has untreated or inadequately treated syphilis at delivery or a reactive treponemal result of the infant/child with clinical findings or a positive RPR test.[4,69,70]

Treatment

Table 140-10 presents the CDC's treatment recommendations.[3] Parenteral penicillin G is the treatment of choice for all stages of syphilis. Because *T. pallidum* multiplies slowly, single doses of short- or intermediate-acting penicillins do not provide the prolonged, low-level exposure to penicillin required for treponeme eradication. As a result, benzathine penicillin G is the only penicillin effective for single-dose therapy.[4,70]

TABLE 140-10

Drug Therapy and Follow-up of Syphilis

Stage/Type of Syphilis	Recommended Regimens[a,b]	Follow-up Serology
Primary, secondary, or early latent syphilis (<1 year's duration)	Adults: Benzathine penicillin G 2.4 million units IM in a single dose Children: Benzathine penicillin G 50,000 units/kg IM in a single dose, up to 2.4 million units	Quantitative nontreponemal tests at 6 and 12 months, with failure if titer does not decrease at least fourfold in 12 months[c]
Late latent syphilis (>1 year's duration), syphilis of unknown duration, tertiary syphilis or retreatment after failure	Adults: Benzathine penicillin G 2.4 million units IM once a week for 3 successive weeks (7.2 million units total) Children: Benzathine penicillin G 50,000 units/kg IM once a week for 3 successive weeks, up to 7.2 million units total	Quantitative nontreponemal tests at 6, 12, and 24 months, with failure if titer does not decrease at least fourfold in 24 months[c]
Neurosyphilis, including ocular or otic involvement	Aqueous crystalline penicillin G 18-24 million units IV (3-4 million units every 4 hours or by continuo us infusion) for 10-14 days[d,f] *or* Aqueous procaine penicillin G 2.4 million units IM daily plus probenecid 500 mg orally four times daily, both for 10-14 days	Repeat CSF examination is no longer required at 6 months if adequate RPR response (decrease by fourfold or greater)
Congenital syphilis (infants with proven or highly probable disease)	Aqueous crystalline penicillin G 50,000 units/kg/dose IV every 12 hours during the first 7 days of life and every 8 hours thereafter for a total of 10 days *or* Procaine penicillin G 50,000 units/kg IM daily for 10 days[d]	Serologic follow-up only recommended if antimicrobials other than penicillin are used
Penicillin-Allergic Patients[e,f]		
Primary, secondary, or early latent syphilis	Doxycycline 100 mg orally two times daily for 14 days *or* Tetracycline 500 mg orally four times daily for 14 days *or* Ceftriaxone 1-2 g IM or IV daily for 10-14 days	Same as for non–penicillin-allergic patients
Late latent syphilis (>1 year's duration) or syphilis of unknown duration	Doxycycline 100 mg orally twice a day for 28 days *or* Tetracycline 500 mg orally four times daily for 28 days	Same as for non–penicillin-allergic patients

[a] Recommendations are those of the CDC.

[b] The CDC recommends that all patients diagnosed with syphilis be tested for HIV infection.

[c] No specific recommendations exist for tertiary syphilis because of the lack of available data.

[d] Some experts administer benzathine penicillin G 2.4 million units IM once per week for up to 3 weeks after completion of the neurosyphilis regimens to provide a total duration of therapy comparable to that used for late syphilis in the absence of neurosyphilis.

[e] For nonpregnant patients; pregnant patients should be treated with penicillin after desensitization.

[f] Growing data support ceftriaxone efficacy, although the optimal dosage and treatment duration are unclear; in neurosyphilis, 2 g IV daily for at least 10 days found to be as effective as intravenous penicillin G in a recent study.

CSF, cerebrospinal fluid.

The recommended treatment for syphilis of less than 1 year's duration is benzathine penicillin G 2.4 million units as a single IM dose. In patients with late syphilis (including those with tertiary syphilis) or of unknown duration, benzathine penicillin G is administered weekly for three successive doses.[4] There is limited data regarding the questionable benefit of additional doses of benzathine penicillin G (or any other antibiotics) for later stages of syphilis.

Neurosyphilis requires more intensive therapy. The preferred regimen is 18 to 24 million units of IV penicillin G per day, administered as 3 to 4 million units every 4 hours or by continuous infusion, for 10 to 14 days. Intramuscular procaine penicillin G 2.4 million units once daily plus probenecid 500 mg orally four times daily is another option when IV administration is not feasible, such as outpatient treatment requiring a peripherally inserted central catheter (PICC) placement. Benzathine penicillin G alone in standard weekly doses does not consistently provide treponemicidal levels in the CSF, resulting in treatment failures. Because *T. pallidum* penicillin resistance has not emerged, the primary need for alternative drugs in treating syphilis is for penicillin-allergic patients.[4]

② Alternative regimens recommended for penicillin-allergic patients are doxycycline 100 mg orally twice daily or tetracycline 500 mg orally four times daily for 2 to 4 weeks depending on the duration of syphilis infection. Parenteral ceftriaxone is another option, particularly because there is a low propensity of cross-reactivity between penicillin and cephalosporins. Ceftriaxone 1 g IV for 10 days was superior to two weekly doses of benzathine penicillin G.[77] In neurosyphilis, ceftriaxone 2 g daily for at least 10 days was as effective as IV penicillin G.[78] Clinicians may avoid ceftriaxone if the penicillin reaction was IgE-mediated or life-threatening (eg, Stevens Johnson Syndrome). Various other beta-lactams have been successfully used to treat syphilis; however, none offer significant advantage over benzathine penicillin G. Azithromycin 2 g as a single dose is no longer recommended due to increasing and unpredictable rates of resistance. Tetracyclines and ceftriaxone should be reserved for cases of documented penicillin allergy and, given concerns regarding patient compliance with these regimens, follow-up serologic testing is particularly important.[4]

For pregnant patients, penicillin is the treatment of choice at the dosage recommended for adults with that particular stage of syphilis. Some clinicians administer an additional IM dose of benzathine penicillin G 2.4 million units 1 week after completion of the recommended regimen, although there is no literature supporting this practice. In women allergic to penicillin, safe and effective alternatives are not available; therefore, skin testing should be performed to confirm a penicillin allergy. Women with positive penicillin skin tests may undergo penicillin desensitization and receive the appropriate treatment regimen for their stage of disease.[4]

Patients treated for primary and secondary syphilis may experience an acute reaction characterized by flu-like symptoms, such as transient headache, fever, chills, malaise, arthralgia, myalgia, tachypnea, peripheral vasodilation, and aggravation of syphilitic lesions, called the Jarisch-Herxheimer reaction. It usually begins within 6 to 8 hours of initiating therapy and lasts 12 to 24 hours. The exact mechanism of the reaction is unknown, although proposed etiologies, including immunologic mechanisms and release of endotoxin or other toxic treponemal products, are not substantiated. The Jarisch-Herxheimer reaction is independent of the drug and dose used and should not be confused with penicillin allergy. Most reactions can be managed symptomatically with analgesics, antipyretics, and rest. Steroids and antihistamines have been administered prior to initiation of syphilitic therapy, but are of limited value.[4,70]

Evaluation of Therapeutic Outcomes

Table 140-10 lists the CDC recommendations for serologic follow-up of patients treated for syphilis.[4] Quantitative nontreponemal tests (eg, RPR) should be performed at 6 and 12 months in all patients treated for primary, secondary, and early non-primary, non-secondary syphilis and at 6, 12, and 24 months for late disease or when duration is unknown. In general, the time to reach seronegativity is proportional to the duration of the disease. Serologic cure is defined by a drop in nontreponemal titers by at least foutfold by 12 months in those treated within a year of infection and by 24 months if the time of exposure cannot be determined or treatment 12 months after infection. Table 140-10 also includes specific testing recommendations for other stages of syphilis. Despite appropriate therapy, about 155% to 20% of patients fail to mount a sufficient antibody titer response. There is limited guidance on the best course of action when this occurs. If the titers were initially low at the time of treatment (eg, 1:2, 1:4), a twofold decline or no change may dictate additional serologic follow-up without retreatment.[4,70,72]

When retreatment is indicated, individuals should receive three weekly treatments of 2.4 million units of IM benzathine penicillin G, excluding neurosyphilis. Retreatment may be indicated when an alternate treatment was used initially, such as doxycycline in a patient without a penicillin-allergy. This differs from treatment of a repeat infection diagnosed within 1 year of exposure, which warrants a single IM dose of benzathine penicillin 2.4 million units. For women treated during pregnancy, monthly quantitative nontreponemal tests are recommended in those at high risk of reinfection. Recent sex partners (within 90 days) of anyone diagnosed should be treated presumptively if serologic tests are not immediately available.[4]

GENITAL HERPES

Epidemiology and Etiology

Genital herpes infections are the predominate cause of genital ulceration in the United States and globally. These infections are primarily attributed to HSV-2, with a prevalence of 11.9% among 14- to 49-year-olds and approximately 572,000 new infections annually.[2,79] The number of individuals with genital herpes is magnified by rising infections caused by HSV-1, usually associated with oropharyngeal disease (eg, “cold sores”).[80] Most persons with HSV-2 are unaware of their infection.[81] Only 30% of those with HSV-1 infection experience clinically recognized outbreaks. HSV-2 rates among women are almost twice that of men. The incidence of HSV-2 is strongly correlated with the start of sexual activity, with rates decreasing gradually in subsequent age groups. Alternatively, HSV-1 is usually acquired earlier in childhood and is inversely proportional to socioeconomic status. Although the number of lifetime sexual partners, age of sexual debut, and STI history correlate with HSV-2 infection, it is commonly transmitted through long-term relationships rather than casual sexual relationships.[82,83]

Genital herpes is of major public health importance, despite most individuals having limited or no manifestations of disease. Although the risk of HSV is higher during clinical outbreaks, most transmission occurs during periods of asymptomatic shedding, hampering prevention efforts. Serious complications, particularly among those with immunosuppression, during pregnancy, and neonates born to mothers with HSV, may occur. For people who experience symptoms, episodes are often recurrent, causing painful ulcers and generalized discomfort for days at a time. A diagnosis of genital herpes may impact sexual relationships, cause social stigma, and lead to psychological distress. For various reasons, the CDC does not recommend screening for HSV in the general population.[3] Similar to syphilis and other STDs, the presence of genital herpes lesions is associated with an increased risk of acquiring HIV following exposure.[4,83–85]

Pathophysiology

HSV-1 and 2 are two members of the Herpesvirus family. Humans are the sole known reservoir for HSV. Each virus is capable of causing clinically indistinguishable infections, although the likelihood of causing disease in a specific anatomic area differs. Infection is transmitted via inoculation of virus from infected secretions onto mucosal surfaces (eg, urethra, oropharynx, cervix, and conjunctivae) or through abraded skin.[4,83–85]

The cycle of HSV infection occurs in five stages: initial mucosal or dermal infection, ganglia infection, establishment of latency, reactivation, and recurrent infection. After cell entry, transportation and replication occurs via viral spread from peripheral sensory nerves to contiguous cells and ganglia, most commonly the sacral nerve root ganglia if genital entry and the trigeminal ganglia if oropharyngeal entry. Chronic infection is established at this time, with clinical latency occurring for the majority of the person’s life. Latency does not mean dormancy, as viral replication occurs in infected neurons and peripheral nerve endings, despite lack of symptoms. These reactivation periods are highly variable among patients. Stress, illness, and sun exposure (UV light) are identified as precipitating factors.[83,84]

Clinical Presentation

The signs and symptoms of genital herpes infection are influenced by many factors, including previous exposure to HSV, viral type, and host factors, such as age and site of infection. Because a high percentage of initial and recurrent infections are asymptomatic, and viral shedding can occur in the absence of apparent lesions or symptoms, identification and education of individuals with genital herpes is essential in controlling transmission. A summary of the clinical presentation of genital herpes is provided in Table 140-11. Those who experience symptoms usually develop multiple painful ulcers, at times accompanied by itching, discomfort, paresthesias, and local lymphadenopathy. These symptoms are typically more severe, involve neurologic complaints (fever, headache, malaise, myalgias), and persist longer in the first episode, especially if they occur during primary infection. Lesions may present at various stages in addition to ulcers, such as vesicles, pustules, and crusting. Frequency of genital herpetic recurrences differ among the HSV types after the first episode, with 90% of those infected with HSV-2 experiencing within the first year in comparison to 55% of HSV-1-infected individuals.[4,83–85]

TABLE 140-11

Presentation of Genital Herpes Infections

General	Incubation period: 2-14 days (mean, 4 days) Can be caused by either HSV-1 or HSV-2
Classification of infection	
First-episode primary	Initial genital infection in individuals lacking antibody to either HSV-1 or HSV-2
First-episode nonprimary	Initial genital infection in individuals with clinical or serologic evidence of prior HSV (usually HSV-1) infection
Recurrent	Appearance of genital lesions at some time following healing of first-episode infection
Signs and symptoms	
First-episode infections	Most primary infections are asymptomatic or minimally symptomatic Multiple painful pustular or ulcerative lesions on external genitalia developing over a period of 7-10 days; lesions heal in 2-4 weeks (mean, 21 days) Flu-like symptoms (eg, fever, headache, malaise) during first few days after appearance of lesions Others—local itching, pain, or discomfort; vaginal or urethral discharge, tender inguinal adenopathy, paresthesias, urinary retention Severity of symptoms greater in females than in males Symptoms are less severe (eg, fewer lesions, more rapid lesion healing, fewer or milder systemic symptoms) with nonprimary infections Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 11-12 days for primary infections and 7 days for non-primary infections
Recurrent	Prodrome seen in approximately 50% of patients prior to appearance of recurrent lesions; mild burning, itching, or tingling are typical prodromal symptoms Compared to primary infections, recurrent infections associated with (1) fewer lesions that are more localized, (2) shorter duration of active infection (lesions heal within 7 days), and (3) milder symptoms Severity of symptoms greater in females than in males Symptoms more severe and prolonged in the immunocompromised On average viral shedding lasts approximately 4 days Asymptomatic viral shedding is more frequent during the first year after infection with HSV
Therapeutic implications of HSV-1 vs HSV-2 genital infection	Primary infections caused by HSV-1 and HSV-2 virtually indistinguishable Recurrent infections and subclinical viral shedding are less frequent with HSV-1 Recurrent infections with HSV-2 tend to be more severe
Complications	Secondary infection of lesions; extragenital infection because of autoinoculation; disseminated infection (primarily in immunocompromised patients); meningitis or encephalitis; neonatal transmission

HSV-1, herpes simplex virus type 1; HSV-2, herpes simplex virus type 2.

Recurrent episodes are usually more localized, have fewer lesions, are shorter in duration, and present with milder symptoms. About half of recurrent ulcers are preceded by prodomal symptoms (mild burning, itching, tingling, or shooting pains), which could extend to the buttocks or leg. Prodromal symptoms may also occur in the absence of genital lesions. Mucocutaneous HSV is detected in these prodromal states, solidifying the evidence that viral reactivation is linked to the symptom presentation. HSV as the cause of atypical presentations can be missed and warrant HSV testing when the clinical picture is uncertain. Education on signs and symptoms of genital herpes to those who were unaware of their seropositivity have resulted in a 48% to 62% observation of classic lesions within the following months, highlighting the knowledge gap among the general public. HSV-1 is associated with a lower rate of asymptomatic and symptomatic recurrence, while HSV-2 is characterized by more frequent recurrences and subclinical shedding.[4,83–85]

Complications

Complications from genital herpes infections resulting from both local autoinoculation and extragenital spread commonly to the eye, rectum, pharynx, and fingers. CNS involvement is seen occasionally and can take several forms, including encephalitis, aseptic meningitis, and transverse myelitis. HSV-2 is more likely to cause aseptic meningitis than HSV-1, while HSV-1 is the most commonly identified cause of acute viral encephalitis.

A major concern is the effect of genital herpes on neonates exposed during pregnancy. Neonatal herpes is associated with a high mortality and significant morbidity. It is transmitted to the newborn primarily through exposure in the birth canal but, in rare cases, transplacentally. The risk of transmission during birth appears much greater for first-episode primary infections than for recurrent infections. Neonatal herpes infection has a case-fatality rate of approximately 50%, with a large proportion of surviving infants experiencing significant morbidity, including permanent neurologic damage. Morbidity and mortality caused by HSV in immunocompromised transplant recipients or those receiving cancer chemotherapy has dramatically reduced by the inclusion of antiviral prophylaxis into most therapeutic plans.[4,83,84]

Diagnosis

Confirmation of genital herpes infection can be made only with laboratory testing. Viral culture and HSV DNA detection with PCR assays are primary modalities used to confirm the diagnosis of first-episode genital herpes as the antibodies produced early in infection may not be detected (complete seroconversion can take months). These tests can also be used when recurrent lesions are present. Although viral culture is highly specific, it is relatively insensitive in detecting HSV in ulcers in the latter stages of healing and in recurrent infections, in part due to reduced viral load. Viral culture is expensive, time-consuming, and improper collection or transport of specimens can result in false-negative results, but may be helpful when acyclovir resistance is suspected. In most situations, HSV isolation from culture takes 48 to 96 hours.[4,83]

PCR assays are the preferred diagnostic tests due to greater sensitivity (in active lesions or asymptomatic viral shedding), significantly faster turnaround, and wider availability. Subtyping should be sought once HSV is detected. Although some PCR tests can differentiate serotype, not all have that capability. Serologic testing plays a role in diagnosis HSV infection in select scenarios: (1) recurrent genital symptoms present with negative PCR/culture; (2) patients with clinical signs of HSV infection without laboratory confirmation; (3) when the partner has documented genital herpes. Type-specific serology can distinguish between HSV-1 and HSV-2 based on HSV-specific glycoprotein G-1 and glycoprotein G-2, respectively. The sensitivity of these tests can vary from 80% to 98%, with false-negatives more likely to occur early in disease. EIAs are the most commonly used tests, which at low index values (1.1-3.0) have high rates of false-positivity. A confirmatory test with another method, such as the Biokit or a western blot, should be performed before interpretation of an EIA, particularly when with low index values.[4,83,84]

Treatment

Management goals for genital herpes include symptom relief, reducing the clinical course to prevent complications and recurrences, and minimizing disease transmission. The CDC recommended genital herpes treatments include the antiviral agents acyclovir, valacyclovir, and famciclovir (Table 140-12). The overall efficacy of these agents is comparable, although patient compliance can be improved with less frequent dosing regimens.[4]

TABLE 140-12

Treatment of Genital Herpes

Type of Infection	Recommended Regimens[a,b]	Alternative Regimens
First clinical episode of genital herpes[c]	Acyclovir 400 mg orally three times daily for 7-10 days,[d] *or* Famciclovir 250 mg orally three times daily for 7-10 days,[d] *or* Valacyclovir 1 g orally twice daily for 7-10 days[d]	Acyclovir 5-10 mg/kg IV every 8 hours for 2 -7 days or until clinical improvement occurs, followed by high-dose oral therapy (valcyclovir 1 g thrice daily) to complete 10-14 days of total therapy[e]
Recurrent infection		
Episodic therapy[f]	Acyclovir 800 mg orally twice daily for 5 days, *or* Acyclovir 800 mg orally three times daily for 2 days, *or* Famciclovir 125 mg orally twice daily for 5 days, *or* Famciclovir 1 g orally twice daily for 1 day, *or* Famciclovir 500 mg orally once, followed by 250 mg orally twice daily for 2 days, *or* Valacyclovir 500 mg orally twice daily for 3 days, *or* Valacyclovir 1 g orally once daily for 5 days	
Suppressive therapy[g]	Acyclovir 400 mg orally twice daily, *or* Famciclovir 250 mg orally twice daily,[h] *or* Valacyclovir 500 mg or 1 g orally once daily[i]	

[a] Recommendations are those of the CDC.

[b] HIV-infected patients can require more aggressive therapy.

[c] Primary or nonprimary first episode.

[d] Treatment duration can be extended if healing is incomplete after 10 days.

[e] Only for patients with severe symptoms or complications that necessitate hospitalization. HSV encephalitis requires 14-21 days of IV therapy.

[f] Requires initiation of therapy within 24 hours of lesion onset or during the prodrome that precedes some outbreaks.

[g] Consider discontinuation of treatment after one year to assess frequency of recurrence.

[h] Famciclovir appears less effective for suppression of viral shedding.

[i] Valacyclovir 500 mg appears less effective than other valacyclovir and acyclovir regimens in patients with 10 or more recurrences per year.

IV, intravenous.

First-Episode Infections

④ Oral formulations of acyclovir, famciclovir, and valacyclovir have demonstrated efficacy in reducing viral shedding, duration of symptoms, and time to healing of first-episode genital herpes infections, with maximal benefits seen when therapy is initiated at the earliest stages of infection. Table 140-10 lists the recommended regimens for first-episode infections. The CDC recommends all patients with first episodes genital herpes receive systemic antiviral therapy to prevent severe or prolonged symptoms associated with newly acquired infections. Additionally, topical antiviral therapy offers minimal clinical benefit and is not recommended. In immunocompromised patients, or those with severe symptoms or complications necessitating hospitalization, parenteral acyclovir is recommended, but has been associated with renal, GI, bone marrow, and CNS toxicity, particularly in patients with renal dysfunction receiving high doses. No antiviral regimen is known to prevent latency or alter the subsequent frequency and severity of recurrences in humans.[4,83–85]

Recurrent Infections

Mild and infrequent recurrences can be managed without pharmacologic therapy. When therapy is warranted or desired, there are two approaches: episodic or chronic suppressive therapy. Episodic therapy is initiated early during the course of the recurrence, preferably within 6 to 12 hours of the onset of prodromal symptoms, but within 24 hours after lesions first appear. Timely episodic therapy can decrease the duration of lesions by 1 to 2 days. Valacyclovir and famciclovir have improved pharmacokinetic profiles versus acyclovir, allowing for reduced dosing frequency and shorter courses. For optimal therapy, providers should prescribe the regimen of choice ahead of recurrences to allow the patient to initiate treatment at home at the first sign of symptoms.[4,83–85]

Table 140-10 lists the recommended suppressive regimens. Daily suppressive therapy may yield a benefit for patients with frequent episodes (≥6 per year), severe recurrences, those who wish to reduce transmission risk to a partner, and to ease anxiety over unpredictable recurrences. Suppressive therapy reduces the frequency and severity of clinical episodes and asymptomatic shedding in 70% to 80% of patients experiencing frequent recurrences. The extent to which suppressive therapy decreases disease transmission to sexual partners remains to be determined. Because the frequency of recurrences tends to diminish over time, periodic “drug holidays” are advocated to assess changes in the underlying recurrence rate and determine if continued suppressive therapy is warranted.[4,83,84]

Selected Populations

Immunocompromised patients are at greatest risk for severe and recurrent HSV infections. Acyclovir, valacyclovir, and famciclovir have been used to prevent reactivation of infection in patients seropositive for HSV who undergo transplantation procedures or induction chemotherapy. Immunocompromised individuals, such as patients with acquired immunodeficiency syndrome (AIDS), who fail treatment or prophylaxis with recommended antiviral doses frequently demonstrate improved response with higher doses. Resistant isolates are a concern in this immunocompromised population, mediated by alterations in viral thymidine kinase. Resistance is conferred to acyclovir, valacyclovir, and, commonly, famciclovir. If resistance is suspected or confirmed with recommended first-line antivirals, foscarnet is usually effective. However, foscarnet is associated with a greater risk of serious adverse effects. Intravenous cidofovir or topical imiquimod may be effective alternatives to forscarnet. Lesional application of an extemporaneous compounded cidofovir (1%) gel or trifluridine ophthalmic solution appears to offer some benefits.[4,83–85]

The safety of famciclovir and valacyclovir during pregnancy is not well established. Acyclovir has been used in pregnant patients and has produced no evidence of teratogenicity. However, levels in amniotic fluid are similar to infants treated with acyclovir, of which 20% develop neutropenia. Because of the high maternal and infant morbidity associated with first-episode primary genital infections or severe recurrent infections at or near term, many clinicians advocate the use of systemic acyclovir as the standard of care in such cases.[4,85,86]

Evaluation of Therapeutic Outcomes

Antivirals can reduce morbidity and improve patient quality of life. Outside of serious conditions, like encephalitis and neonatal infection, these agents are palliative. CDC guidelines suggest discontinuation of suppressive therapy after 1 year should be considered to assess for possible changes in the patient’s intrinsic pattern of recurrence. In most patients, decreases in recurrence rates and severity of symptoms occur over time. However, some clinicians prefer to continue suppressive therapy indefinitely because it significantly reduces asymptomatic viral shedding, reducing the risk of disease transmission to uninfected sexual partners.[4]

Education on the natural course of the infection, reinforcing accurate information, and dispelling misconceptions can significantly improve a patient's experience with HSV. Descriptions of typical and atypical presentations can empower patients to initiate therapy early and minimize anxiety. Prevention strategies should be emphasized, highlighting disclosure to partner(s), abstaining from sexual activity when active lesions are present, condom use, and antiviral therapy.[83,84]

HUMAN PAPILLOMAVIRUS INFECTIONS

Epidemiology and Etiology

In 2018, the CDC estimated there were 43 million HPV infections in the United States, 13 million of which were new infections.[5] However, as HPV is not a reportable condition, the incidence is likely much higher. HPV accounts for approximately 50% of new STIs each year.[2] Over 40% of women have evidence of HPV infection, with incidence peaking in teens and early twenties, aligning with initiation of sexual activity.[5] Additionally, lifetime risk of acquiring an HPV infection is over 80%, and risk increases with number of sexual partners.[86] Since the introduction of the HPV vaccine, incidence of HPV infections in teen girls and women in their early twenties have decreased.[87] Persistent infection with some HPV types can cause genital warts and cancer, and reinfection is common, especially in young, sexually active populations.

More than 125 HPV types have been characterized and over 40 are associated with genital tract lesions. Of these, infection with types 6 and 11 most commonly develop low-grade dysplasia manifested as genital warts. Infection with several HPV types, particularly HPV-16 and HPV-18, is associated with cervical neoplasma, the second most common cancer in women worldwide and account for approximately 66% cervical cancers in the United States.[4,5,88] The WHO estimates that 84% of HPV lesions are represented as cervical cancers worldwide.[89] Persistent carriers of oncogenic HPV strains, in combination with a variety of other factors including immunosuppression, smoking, chlamydial infection, may all play a role in promotion of viral persistence and cancer.[88] Additionally, women living with HIV are six times more likely to develop cervical cancer compared to women without HIV.[90,91]

Pathophysiology

HPV is a double-stranded DNA virus that targets basal epithelial cells. It enters cells through a break in the epithelium, and replicates within basal cells as it differentiates and progresses to the epithelial surface. Virus is shed with dead keratinocytes and infection is transmitted via contact dead keratinocyte or free virions. In a wart, viral replication is associated with excessive proliferation of all epidermal layers, except the basal layer, whereas malignant HPV disease is associated with proliferation of basal cells. HPV is transmitted by sexual intercourse, including oral sex, and may also be spread by touching an infected partner's genitalia.[88,89]

Clinical Presentation

In most individuals, genital infection with HPV is subclinical and self-limited, clearing within 6 to 9 months. HPV can infect genitalia of both women and men, as well as perianal, anal, and oropharynx regions in both genders. Approximately 1% of all infected individuals develop genital warts. When present, genital warts can be large and multifocal, producing variable degrees of discomfort. Appearance of genital warts may differ based on gender and anatomic site. For example, penile warts may be slightly raised with a rough pigmented surface, while vulvar warts are usually soft and whitish. Based on HPV DNA detection methods, most warts will regress spontaneously within 1 to 2 years of their initial appearance. HPV, while known for links to cervical cancer, can also cause cancer of the anus, penis, vulva, vagina, and oropharynx, but are less common.[4,88,89]

Diagnosis

Anogenital warts are diagnosed clinically and confirmed by biopsy in cases where the diagnosis is uncertain, when warts do not respond to standard treatment, or the patient is immunocompromised. The Papanicolaou smear (Pap smear) is the most frequently used and cost-effective diagnostic test for detecting clinical and subclinical HPV in women. However, Pap smears are neither specific for HPV nor useful in detecting latent infections. Various tests for detecting HPV DNA, RNA, or capsid protein also are available, and unlike the Pap smear do not require subjective interpretation of the results. The HPV-specific tests are only approved in women with abnormal Pap smears or women older than 30 years. However, use of HPV DNA testing as a routine screening test in lieu of Pap smears is expected in the near future. In women identified to have high-risk HPV strain infections, follow-up cytology is performed. HPV tests are not approved for use in men and are not indicated as a screening tool for STIs.[4,88,89]

Routine screening for cervical cancer is recommended for all persons with a cervix, regardless of gender identity or partner preference. Age recommendations vary by organization. The USPSTF and the American College of Obstetricians and Gynecologists (ACOG) recommend routine cervical cancer screening every 3 years for all persons with a cervix ages 21 to 65 regardless of vaccination status. For women 30 to 65, screening can also include one of several FDA-approved oncogenic or high-risk HPV tests. The American Cancer Society recommends cervical screening any persons with a cervix, regardless of gender identity, ages 25 to 65 by combining a Pap test with an HPV test or a Pap test alone every 3 years.[91–93] Data is insufficient to recommend routine anal cancer screening. An annual digital anorectal exams (DARE) may be useful in high-risk patient populations for early detection of HPV. The updated CDC STI Guidelines provide a table detailing the screening recommendations from various organizations.[4]

Treatment

No consensus exists regarding the best treatment approach for patients with genital HPV infection, particularly because most cases appear to be transient with spontaneous regression of lesions. A number of treatments are recommended (see Table 140-13), but none are clearly superior. Treatment is directed toward patients with manifestations of genital warts, with the goal of removing or destroying lesions and grossly infected surrounding tissue. Shared decision making between patient and provider determine the decision to treat and utilization of patient or provider applied therapy. Type of therapy is depended upon lesion location, provider experience, patient preference, and availability. Provider-applied therapies, cryotherapy and surgical removal, are options for any site, while acid treatments are options for vaginal, cervical, and intra-anal warts. Many patients will require multiple courses of therapy. Because such treatments neither stop viral expression in surrounding tissue nor eliminate viral latency, recurrence of lesions is common.[4]

TABLE 140-13

Treatment Regimens for Miscellaneous Sexually Transmitted Infections

Infection	Recommended Regimens[a]	Alternative Regimens
Cervicitis[b]	Doxycycline 100 mg orally twice daily for 7 days	Azithromycin 1 g orally in a single dose
Epididymitis Acute infection most likely caused by C. trachomatis or *N. gonorrhoeae* Acute infection most likely caused by *C. trachomatis, N. gonorrhoeae,* or enteric organisms (men who practice insertive anal sex) Acute infection most likely caused by enteric organisms only	Ceftriaxone 500 mg IM in a single dose PLUS doxycycline 100 mg orally twice daily for 7 days Ceftriaxone 500 mg IM in a single dose PLUS levofloxacin 500 mg orally daily for 10 days Levofloxacin 500 mg orally daily for 10 days	
Lymphogranuloma venereum	Doxycycline 100 mg orally twice daily for 21 days[c]	Azithromycin 1 g weekly for 3 weeks or erythromycin base 500 mg orally four times daily for 21 days[c,d]
Nongonococcal urethritis (NGU)	Doxycycline 100 mg orally twice daily for 7 days	Azithromycin 1 g orally in a single dose or 500 mg orally in a single dose followed by 250 mg daily for 4 days
NGU (Persistent or recurrent or due to *Mycoplasma genitalium*)	Doxycycline 100 mg orally twice daily for 7 days followed by moxifloxacin 400 mg orally daily for 7 days	If azithromycin resistance can be ruled out, moxifloxacin may be substituted with oral azithromycin 1 g and then 500 mg daily for 3

		days
HPV infection		
External genital/perianal warts	*Provider-Administered Therapies:* Cryotherapy (eg, liquid nitrogen or cryoprobe); repeat weekly as necessary, *or* TCA 80%-90% *or* BCA 80%-90% applied to warts; repeat weekly as necessary, *or* Surgical removal (tangential scissor excision, tangential shave excision, curettage, or electrosurgery) *Patient-Applied Therapies:* Podofilox 0.5% solution or gel applied twice daily for 3 days, followed by 4 days of no therapy; cycle is repeated as necessary for up to four cycles. Imiquimod 3.75% or 5% cream applied at bedtime three times weekly for up to 16 weeks,[e,f] *or* Sinecatechins 15% ointment applied three times daily for up to 16 weeks	
Vaginal and anal warts	Cryotherapy with liquid nitrogen, or TCA or BCA 80%-90% as for external HPV warts; repeat weekly as necessary Surgical removal (not for vagina l or urethral meatus warts)	
Urethral meatus warts	Cryotherapy with liquid nitrogen, or surgical removal	
Prevention (ages 9-14 years)	Gardasil9® (HPV 9-valent [type s 6, 11, 16, 18, 31, 33, 45, 52, 58]) recombinant vaccine 0.5 mL IM on day 1; a second dose administered 6-12 months following the first dose[f]	
Prevention (age ≥15-26 years)	Gardasil (HPV 9-valent [types 6, 11, 16, 18, 31, 33, 45, 52, 58]) recombinant vaccine 0.5 mL IM on day 1; a second and third dose are administered 1 and 6 months following the first dose	

[a] Recommendations are those of the CDC.

[b] Consider concurrent treatment for gonorrhea infection if the patient is at risk for gonorrhea.

[c] Pregnant patients should be treated with erythromycin.

[d] If NGU is due to Chlamydia trachomatis, refer to treatment in Table 140-8 . If NGU not due to C. trachomatis, consider HSV, trichomoniasis, Mycoplasma genitalium, or HPV as potential causes of NGU and perform testing when appropriate.

[e] Safety during pregnancy is not established. BCA, bichloracetic acid; HPV, human papillomavirus; TCA, trichloroacetic acid.

[f] CDC recommendations: vaccination is recommended in adolescents 11-12 years of age, and can be given as early as age 9. Catch up vaccination is recommended through age 26 years for those who either were not previously vaccinated, or who did not complete the vaccination series. Vaccination for adults ages 27-45 can be considered.

Vaccination

As lesions are difficult to successfully treat, high incidence of reinfection, and concern for malignancy with persistent infections, the focus of HPV treatment is primarily on prevention. The only way to avoid acquiring HPV is to abstain from any type of sexual activity; however, barrier contraceptive methods may help decrease the risk of HPV transmission. Therefore, three HPV vaccines are licensed in the United States and endorsed by the CDC and Advisory Committee on Immunization Practices (ACIP).[94] The vaccines cover the most common and virulent HPV strains. Cervarix (a bivalent vaccine for HPV-16 and 18), Gardasil (a quadrivalent vaccine (4vHPV) for HPV-6, 11, 16, and 18), and Gardasil 9 (a 9-valent (9vHPV) vaccine for HPV-6, 11, 16, 18, 31, 33, 45, 52, and 58) are all indicated for preventing cervical precancers and cervical cancer in females 9 to 26 years of age. The 9vHPV vaccine offers protection against 7 oncogenic strains of HPV, which accounts for approximately 80% of cervical cancers.[95] In addition, 4vHPV and 9vHPV are indicated in unvaccinated males 9 to 26 years of age.[94]The FDA extended approval for use of the 9vHPV for women and men ages 27 to 45 years and in 2019 the ACIP recommended that adults in that age group discuss receiving the HPV vaccine with their provider through shared decision making.[94] For women and men ages 30 to 45 years, the cost-effectiveness of HPV vaccination should be considered as vaccination may provide limited health benefit at the population level.[96] All three vaccines are equally recommended by the ACIP; however, only 9vHPV vaccine is available for sale within the United States.[94,95]

Although it is ideal to vaccinate patients prior to the onset of sexual activity, those infected with one or more HPV types may still receive protection from vaccination.[4] Additionally, while the vaccine indication is cervical cancers prevention, males are included in the recommendations to reduce spread of asymptomatic disease and reduce risk of HPV-related malignancies.

Previously, all vaccines were administered as a three-dose series over 6 months, but in 2016 ACIP recommendation changed for patients less than 15 years to a two-dose schedule at 0 and 6 to 12 months. Data in women aged 16 to 26 years supports the use of a two-dose schedule in those 9 to 14 years old, instead of the three-dose schedule, as antibody response with two doses was non-inferior to three doses. All other age groups are recommended to receive the three-dose series at 0, 2, and 6 months.[94,96–99]

The safety profile of the HPV vaccines has been well established over the past decade.[99–102] The CDC and FDA continuously monitor the safety of vaccines via program such as Vaccine Adverse Event Reporting System (VAERS), Vaccine Safety Data link, and Clinical Immunization Safety Assessment Project.[100] The most common adverse events are related to injection site reactions, including pain, redness, or swelling. Additionally, patients may also report fever, headache, asthenia, nausea, or muscle or joint pain. Early VAERS data showed high rates of syncope. Syncope is a known adverse event after any injectable vaccination, and adolescents are also more likely to experience syncope after a medical procedure, including vaccination. In response, the FDA, CDC, and ACIP recommend to observe all patients for 15 minutes after administration of the vaccine to monitor for syncope, taking appropriate precautions to prevent falls and injuries from fainting. Over 90% of health events reported to VAERS were classified as nonserious.[1,100] HPV vaccination has not been linked to new autoimmune diseases or neurologic disorders.[99–101]

The main goal of HPV vaccination is to prevent HPV-associated malignancies; however, time from HPV infection to cervical cancer may exceed 20 years, so effects of the vaccine may not be seen for some time.[88,100] Although the ability to measure effect of the vaccine on malignancies is limited, introduction of the vaccines has substantially reduced HPV prevalence and HPV-related diseases.[5,103] There was substantially reduced risk of cervical cancer among Swedish girls ages 10 to 30 vaccinated with the quadrivalent HPV vaccine.[103] There have also been concerns regarding the long-term effect of the vaccine given the young age at which it is recommended to be administered. Antibody titers maintain appropriate levels for approximately 10 years and there is no evidence to suggest that protection decreases with time.[86] Patients should be vaccinated prior to onset of sexual activity to gain the greatest protection from the vaccine for the duration of time when they are at highest risk. As mentioned, the vaccine may still be protective even after patients have become sexually active.

Despite CDC and ACIP recommendations, the number of adolescents receiving the vaccine is below the desired threshold of 80%.[7,102,104,105] However, numbers are increasing. Girls aged 13 to 17, 70% received at least one dose of the vaccine and 54% received the entire series. The numbers are lower for boys, with 66% receiving at least one dose and 49% receiving all three.[102] Rates of vaccine implementation may increase with interventions, such as patient education and reminders, but a barrier still exists introducing this vaccine into a nontraditional target population.[105,106]

Other STIs

Several STIs other than those just discussed occur with varying frequency in the United States and throughout the world. Although an in-depth discussion of these diseases is beyond the scope of this chapter, Table 135-13 lists recommended treatment regimens.[4]

ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
BCA	bichloracetic acid
CDC	Centers for Disease Control and Prevention
CNS	central nervous system
CSF	cerebrospinal fluid
DARE	digital anorectal exam
DGI	disseminated gonococcal infection
DNA	deoxyribonucleic acid
EIA	enzyme immunoassay
EPT	expedited partner therapy
FDA	Food and Drug Administration
FTA-ABS	fluorescent treponemal antibody absorption
GI	gastrointestinal
HIV	human immunodeficiency virus
HPV	human papillomavirus
HSV	herpes simplex virus
HSV-1	herpes simplex virus type 1
HSV-2	herpes simplex virus type 2
IHPS	infantile hypertrophic pyloric stenosis
IM	intramuscular
IV	intravenous
MSM	men who have sex with men
NAATs	nucleic acid amplification tests

NGU	nongonococcal urethritis
Pap	Papanicolaou smear
PCR	polymerase chain reaction
PID	pelvic inflammatory disease
PMN	polymorphonuclear
RPR	rapid plasma reagin
STI	sexually transmitted infection
TCA	Trichloroacetic acid
TOC	test of cure
TPPA	*T. pallidum* particle agglutination assay
USPSTF	US Preventative Services Task Force
VAERS	Vaccine Adverse Event Reporting System
VDRL	Venereal Disease Research Laboratory

SELF-ASSESSMENT QUESTIONS

1. Which of the following age groups represent the highest proportion of new STIs?

A 15 to 24 years old

B 25 to 34 years old

C 35 to 54 years old

D ≥ 55 years old

2. When taking a sexual history, it is important to consider the five Ps. Which of the following are not included in the five Ps patient assessment?

A Partners

B Practices

C Providers

D Protection

3. Which of the following is the recommended treatment for a 22-year-old 65 kg female diagnosed with a cervical gonococcal infection? The patient tested negative for chlamydia and has no known drug allergies.

A Ceftriaxone 500 mg IM × 1 dose

B Cefixime 800 mg PO × 1 dose and doxycycline 100 mg orally twice daily × 7 days

C Ceftriaxone 500 mg IM × 1 dose and azithromycin 1,000 mg orally × 1 dose

D Ciprofloxacin 500 mg orally twice daily × 7 days

4. A 20-year-old male presents to the clinic with purulent urethral discharge and a positive urine NAAT for gonorrhea and chlamydia. When taking a sexual history, the patient discloses two sexual partners in the past 60 days, one male and one female. To the patient's knowledge, neither partner is experiencing symptoms. The patient is provided first-line therapy for gonorrhea and chlamydia in the clinic. In addition to referral for medical care, which of the following strategies are most appropriate for partner management?

A Offer expedited partner therapy for both partners.

B Offer expedited partner therapy only for the female partner as use is cautioned for the male patient.

C Offer expedited partner therapy only for the male partner as use is cautioned for the female patient.

D Expedited partner therapy is inappropriate for both patients.

5. After successful treatment for uncomplicated genital chlamydia infection, which of the following are recommended for patients without persistent or recurrent symptoms?

A Retest 3 months after completion of therapy

B Test of cure NAAT at conclusion of therapy

C Culture and sensitivity testing in combination with test of cure NAAT at conclusion of therapy

D No follow-up testing necessary

6. Which of the following regimens is recommended for treatment of *C. trachomatis* rectal infections?

A Ciprofloxacin 500 mg orally twice a day for 7 days

B Azithromycin 1 g orally as a single dose

C Doxycycline 100 mg orally twice a day for 7 days

D Erythromycin base 500 mg orally four times a day for 7 days

7. Which of the following statements regarding trichomoniasis is true?

A Only sexual transmission of trichomoniasis is possible.

B The majority of infected men are symptomatic.

C Vaginal discharge is rare among symptomatic women.

D NAAT testing for trichomoniasis is preferred to wet-mount specimen examination.

8. Of the following treatment regimens, which is (are) recommended by the CDC for treating a patient with trichomoniasis who fails initial treatment with metronidazole 500 mg orally twice daily for 7 days and reinfection has been excluded?

A Tinidazole 2 g orally as a single dose

B Metronidazole 500 mg orally twice a day for 7 days

C Metronidazole 2 g orally for 3 to 5 days

D Tinidazole 2 g orally for 7 days

9. Which of the following organisms may be suspected in patients with persistent symptoms of pelvic inflammatory disease who have received treatment with ceftriaxone, doxycycline, and metronidazole?

A *Treponema pallidum*

B *Mycoplasma genitalium*

C *Group B streptococcus*

D *Chlamydia trachomatis*

10. Which of the following are a complication of pelvic inflammatory disease?

A Persistent pelvic pain

B Ectopic pregnancy

C Infertility

D All of the above

11. The CDC recommends that a penicillin-allergic pregnant patient with a diagnosis of primary syphilis should be treated with

A Azithromycin

B Doxycycline

C Erythromycin

D Penicillin desensitization

12. A 21-year-old man with no known drug allergies who is receiving HIV preexposure prophylaxis (PrEP) is seen for routine follow-up visit. Screening laboratory tests show a positive treponemal enzyme immunoassay (EIA) and a positive RPR with a titer of 1:16. He does not have any symptoms and does not recall any symptoms over the past year and states he has never been diagnosed with syphilis. His screening tests 6 months ago were negative. What is the most appropriate management of syphilis for this patient?

A No treatment is necessary since he is asymptomatic.

B Benzathine penicillin G 2.4 million unites intramuscular as a single dose.

C Benzathine penicillin G 2.4 million unites intramuscular weekly for 3 weeks.

D Ceftriaxone 1 g intramuscular daily for 10 days.

13. Which of the following statements regarding genital herpes infection is false?

A Most genital infections are caused by HSV-2.

B Clinical manifestations of infection can occur within 2 days following exposure.

C Asymptomatic viral shedding is considered the most important source of transmission.

D Routine screening for HSV-1 and HSV-2 infections is recommended for asymptomatic patients ages 15 to 24.

14. A 32-year-old woman presents for counseling regarding management of recurrent genital herpes. She has had three episodes in the past 11 months and is interested in reducing her risk of recurrence as well as reducing her risk of transmisison to her new partner. Which of the following regimen is most appropriate to reduce genital HSV recurrence?

A Episodic therapy with famciclovir 125 mg orally two times a day × 5 days

B Episodic therapy with acyclovir 400 mg orally three times a day for 5 days

C Suppressive therapy with valacyclovir 500 mg orally once daily

D Suppressive therapy with valacyclovir 1000 mg orally three times weekly

15. Which of the following statements regarding human papillomavirus (HPV) vaccination is false?

A HPV vaccination has not been shown to decrease cervical cancer rates

B HPV vaccination is indicated for anyone who has not completed the HPV vaccination series through age 26

C Adults ages 27 to 45 may decide to receive HPV vaccination based on discussion with their clinician if they were not previously vaccinated

D HPV vaccination is indicated, even if someone has tested positive for HPV

SELF-ASSESSMENT QUESTIONS-ANSWERS

1. A. In 2018, the highest rates of new STIs were acquired by teens and young adults aged 15-24 years old.
2. C. The five Ps include: partners, practices, protection, past STIs, and prevention of pregnancy strategies.
3. A. First-line recommended therapy for uncomplicated cervical gonorrhea is now 500 mg of ceftriaxone given intramuscularly once. This increased dose of ceftriaxone better attains pharmacokinetic and pharmacodynamic targets for *N. gonorrhoeae*. Additionally, single- drug therapy is now recommended versus dual therapy to address rising azithromycin resistance and reduce collateral damage to the human microbiome. If chlamydial infection cannot be ruled out, however, dual therapy is recommended with the addition of doxycycline. Intramuscular ceftriaxone is preferred over oral cefixime. Due to fluoroquinolone resistance rates, ciprofloxacin is no longer recommended for treatment of gonorrhea.
4. B. Expedited partner therapy (EPT) with oral cefixime 800 mg once and doxycycline 100 mg twice daily × 7 days is appropriate for uncomplicated gonococcal infections. Females with symptoms of pelvic inflammatory disease are contraindicated for EPT, but this patient’s female partner dose not describe symptoms. EPT should be used with caution in men who have sex with men due to high rates of HIV and syphilis co-infection and inadequate data in this patient population. Both partners should be referred for medical evaluation.
5. A. Posttreatment laboratory testing (ie, NAAT or culture and sensitivity) for therapeutic failure is not recommended unless symptoms persist, concern for non-adherence, or in pregnancy. Due to high risk of reinfection, all patients who have been treated for chlamydia should be retested approximately 3 months after treatment. Posttreatment tests should be performed 3 weeks after completion of therapy due to false positives with continued presence of nonviable organisms.
6. C. Oral doxycycline 100 mg twice daily × 7 days and azithromycin 1 g as a single dose are both recommended treatments for uncomplicated

chlamydia infections. However, there are efficacy concerns with the azithromycin regimen in rectal chlamydia. Therefore, doxycycline is now the preferred regimen. Ciprofloxacin and erythromycin are alternative options.

7. D. Non-sexual transmission of trichomoniasis is possible, but the overwhelming majority of cases are transmitted via sexual contact. Men rarely present with symptoms of trichomoniasis, compared to women who the majority are symptomatic most commonly with vaginal discharge. NAAT testing is now preferred to wet-mount examination as it is more sensitive versus wet-mount examinations.

8. B. Metronidazole 500 mg orally twice daily for 7 days is now the recommended first-line regimen for female patients with trichomoniasis. A second 7-day course of metronidazole is recommended if initial therapy fails. Metronidazole 2 g orally for 7 days or tinidazole 2 g orally for 7 days are options if infection persists and reinfection is ruled out.

9. B. Mycoplasma genitalium is an emerging cause of urogenital infections and should be considered in symptomatic patients who do not respond to therapy targeted at gonorrhea, chlamydia, or anaerobes. Untreated M. genitalium infection increases risk of complications, including pelvic inflammatory disease.

10. D. PID is an inflammatory disorder of the upper female genital tract and can include any combination of complications that may result in long-term reproductive damage.

11. D. Doxycycline in non-pregnant patients is an acceptable alternative to penicillin for the treatment of primary syphilis. Macrolides are no longer recommended as alternatives due to increasing concerns for resistance. For pregnant patients, penicillin is the only recommended therapy and penicillin desensitization is appropriate.

12. B. The patient in this case has early non-primary, non-secondary syphilis (formerly early latent syphilis) since he has positive serologic tests without clinical symptoms and a negative test in the past 6 months (<1 year). Even if patients are asymptomatic, treatment is recommended. Benzathine penicillin G 2.4 million units intramuscularly.

13. D. Routine screening is not indicated for the general population. However, patients with no history of genital herpes, but whose partner has genital herpes may benefit from screening to determine risk of infection and to guide counseling. Additionally, patients who present for an STD evaluation, especially those with multiple sex partners, patients with HIV infection, and MSM may benefit from HSV screening as they may be at increased risk of HIV acquisition and other STIs.

14. C. Daily suppressive therapy can provide symptomatic relief by reducing frequency of recurrence and may be effective at reducing subclinical viral shedding. Suppressive therapy is preferred for those with frequent recurrences and in serodiscordant partners. Valacyclovir 500 mg or 1000 mg daily, famciclovir 250 mg twice daily, or acyclovir 400 mg twice daily are the recommended suppressive regimens.

15. A. HPV vaccination has been shown to decrease rates of cervical cancer and genital warts. HPV vaccination is indicated in patients ages 9 to 26, and may be considered in those ages 27 to 45 based on shared clinical decision making. Regardless of a patient's previous HPV infection history, vaccination may still prevent against additional strains.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 141: Bone and Joint Infections

Bryan T. Alexander; Scott J. Bergman

KEY CONCEPTS

KEY CONCEPTS

①The most common cause of osteomyelitis (particularly that acquired by hematogenous spread) and infectious arthritis is *Staphylococcus aureus* (*S. aureus*).

②Culture and susceptibility information are essential as a guide for antimicrobial treatment of osteomyelitis and infectious arthritis.

③Joint aspiration and examination of synovial fluid are extremely important to evaluate the possibility of infectious arthritis.

④The most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time.

⑤Antibiotics generally are given in high doses so that adequate antimicrobial concentrations are reached within the infected bone and joints.

⑥Oral antimicrobial therapies can be used for osteomyelitis to follow a parenteral regimen in children who have a good clinical response to IV antibiotics and in adults without diabetes mellitus or peripheral vascular disease when the organism is susceptible to the oral antimicrobial, a suitable oral agent is available, and adherence is ensured.

⑦The standard duration of antimicrobial treatment for acute osteomyelitis is 4 to 6 weeks.

⑧The three most important therapeutic approaches to the management of infectious arthritis are appropriate antibiotics, joint drainage, and joint rest.

⑨Monitoring of antibiotic therapy is important and typically involves noting clinical signs of inflammation, periodic white blood cell (WBC) counts, C-reactive protein, and erythrocyte sedimentation rate (ESR) determinations.

BEYOND THE BOOK

BEYOND THE BOOK

Activity #1 The long-acting lipoglycopeptide antibiotics, dalbavancin and oritavancin, are potentially useful treatments for bone and joint infections because of their infrequent dosing and gram-positive spectrum of activity. Conduct a literature search to identify one primary research report published on these agents in the last 2 years. If the manuscript provides data on the safety or effectiveness of these drugs in treating deep-seated infection for longer than 2 weeks, reflect on the advantages and disadvantages for this type of treatment strategy.

Activity #2 The OVIVA trial, as discussed in the chapter, was a practice changing study for many clinicians and has significantly motivated the process of shifting more treatment courses for bone and joint infections away from IV agents, which require OPAT, toward appropriate oral regimens. However, the results of this trial aren't applicable to all clinical situations that arise. Review the OVIVA study methods, results, and conclusions (https://www.nejm.org/doi/full/10.1056/NEJMoa1710926) and make a list of the clinical situations and oral regimens for which these study results may apply. This will help you advocate for the use of oral therapy in the most appropriate circumstances.

INTRODUCTION

Bone and joint infections are comprised of two disease processes known, respectively, as *osteomyelitis* and *septic* or *infectious arthritis*. They are unique and separate infectious entities with different signs and symptoms and infecting organisms. Prosthetic joint infections, resulting from the advancement of modern technology, are distinct and blend attributes of each disease. Despite therapy, these infections all cause significant morbidity from residual damage with chronic or recurring infections. Emphasis on initiating antibiotic therapy, targeted to the most likely pathogens, as soon as possible is important in reducing long-term complications.

EPIDEMIOLOGY

Osteomyelitis

① Osteomyelitis has historically been an uncommon disease. One classic publication reported that 247 patients had osteomyelitis in a prominent American teaching hospital during a 4-year period.[1] In Spain there were more than 500 cases of osteoarticular infections per year over the course of a decade.[2] Over that time, the incidence increased from 11.4 to 24.4 cases per 100,000 person-years.[3] Acute osteomyelitis has an annual incidence of 0.4 per 1,000 children. Osteomyelitis cases have been rising in adults due to an aging population having more cases of diabetic foot infections and prosthetic joint replacements. Osteomyelitis can be caused by contiguous spread, including postoperative contamination, direct puncture from trauma, or associated with adjacent soft tissue infections which is the most common source. Hematogenous osteomyelitis comprises 19% of infections, and osteomyelitis occurring in patients with significant peripheral vascular disease comprises 34% of infections.

The bacteriology of hematogenous osteomyelitis is unique, in that one pathogen, *S. aureus*, is responsible for more than 80% of these infections. Streptococci and *Escherichia coli* (*E. coli*) make up the remainder in most of the population. One exception is in children 3 months to 4 years of age. With the advent of molecular diagnostics, *Kingella kingae* (*K. kingae*), an organism that is part of the oral microbiota, has been identified as a common cause of preschool osteoarticular infections.[4] After children reach the age of 4 years, *S. aureus* again accounts for nearly 80% of infections. *Haemophilus influenzae* type b used to be an important pathogen but has been almost completely eliminated with the use of the conjugate vaccine. Osteomyelitis in neonates can result from organisms transferred from the mother at birth such as Group B *Streptococcus*, and *E. coli*, but is most commonly from infection with *S. aureus*.

Vertebral osteomyelitis occurs through hematogenous spread and has several unique features, being most common in adults over 50 years of age and often misdiagnosed initially. It typically presents with recalcitrant back pain unresponsive to usual symptomatic therapies, elevated inflammatory markers, and sometimes fever.[5] The lumbar and thoracic regions are the locations of most infections. Infections are most likely to develop in the vascular areas near the subchondral plate region of the vertebral body. These infections are typically monomicrobial and are caused principally by Staphylococci.[5] Gram-negative organisms, most commonly the Enterobacterales, *E. coli,* and *Klebsiella pneumoniae,* that originate within the urinary tract or intraabdominal cavity are more common in older patients.[7] *Mycobacterium tuberculosis* and fungi also are known to cause infections in the spine, albeit rarely. Skin and respiratory tract infections are other sources of infection known to lead to vertebral infections.

Contiguous-spread disease has several important differences compared with hematogenous osteomyelitis. Although *S. aureus* is still the most common organism isolated, polymicrobial infections occur more often than with hematogenous osteomyelitis. *Streptococcus, Staphylococcus epidermidis*, *E. coli*, *Pseudomonas aeruginosa* (*P. aeruginosa*), and anaerobes can also be isolated.

Patients with diabetes mellitus frequently have infections that involve the foot. Cases extending to the bone may result in mixed infection, including with gram-negative bacilli. Puncture injuries to the foot, causing osteochondritis, are another reason for gram-negative infection, sometimes caused by *P. aeruginosa*. *S. aureus* remains a significant pathogen in these patients due to its prevalence on the skin. When anaerobes are grown from cultures, they usually are found in association with other organisms, including aerobic bacteria. *Bacteroides fragilis* comprises the majority of anaerobic isolates. Predisposing factors in patients who have anaerobic osteomyelitis include vascular disease, peripheral neuropathy, trauma, bites, or contiguous infections such as abscess.

Infectious Arthritis

Infectious or septic arthritis is an inflammatory reaction within the joint space. Septic arthritis is one of the most common causes of new cases of arthritis. The incidence of proven or likely septic arthritis is 4 to 10 cases per 100,000 patient-years. The incidence of septic arthritis increases 10-fold among patients that have rheumatoid arthritis.[8]

Although relatively infrequent, neonates can have infectious arthritis because of a broad range of organisms similar to osteomyelitis, with *S. aureus*, Group B *Streptococcus,* and *E. coli* being most common. *K. kingae* is now considered predominant in those 6 months to 4 years old while *S. aureus* is the most common pathogen in children 4 years of age and older.[9] Pneumococcal arthritis is decreasing in incidence as a result of conjugate pneumococcal vaccine administration to infants.[10] If the child has not been fully vaccinated or is immunocompromised, *S. pneumoniae* or *H. influenzae* type b may be a cause.

Some organisms, such as *S. aureus* and *Neisseria gonorrhoeae*, are especially likely to infect a joint during bacteremia. Gonococcal arthritis is a common manifestation of disseminated gonococcal infection, occasionally with associated osteomyelitis.[11] Gonococcal arthritis is now uncommon in North America and Europe, although it remains an important concern in developing countries.

Within the adult population, *S. aureus* is responsible for the majority of arthritis cases.[12] Streptococcal infections are the second most common, followed by gram-negative organisms. Among the latter, *E. coli* is the most common; however, *P. aeruginosa* can be seen in special situations such as in intravenous drug users or nosocomial infections.

Although rare, infectious arthritis can be caused by fungi, mycobacteria, or viruses such as varicella-zoster, rubella, or parvovirus.[13] Penetrating injury of the joint can result in an infection due to *Pasteurella* or *Capnocytophaga* from dog or cat bites, *Eikanella* in human bites, or *Pantoea* when the injury is induced by a thorn.

ETIOLOGY

Osteomyelitis

The most common method of classifying osteomyelitis is based on the mode of acquisition of the bone infection. Disease that results from spread through the bloodstream is termed hematogenous osteomyelitis, while that reaching the bone from an adjoining soft tissue infection is termed *contiguous osteomyelitis*. Patients with peripheral vascular disease are at risk for the development of contiguous osteomyelitis, and they present unique management features so are sometimes classified separately. Osteomyelitis that results from direct inoculation, such as from trauma, puncture wounds, or surgery, generally is also classified as inoculation osteomyelitis.

Osteomyelitis also can be classified based on the duration of the disease. Acute osteomyelitis describes infections of recent onset, with symptoms usually present about one week, whereas chronic infections are those of a longer duration. Some authors describe chronic infections as those with symptoms for more than 1 month before therapy, while other authors define chronic infections as any relapse of an initial infection. Hematogenous osteomyelitis almost always involves one bone whereas contiguous osteomyelitis can present in multiple bones, especially when vascular insufficiency is an underlying risk factor.

Infectious Arthritis

Most infecting organisms produce an infection in a single joint, termed *monoarticular infection*; however, infections also can involve two or more joints, especially when associated with bacteremia. As with osteomyelitis, joint infections also can be classified according to the mechanisms by which the infecting organism reaches the joint. Infectious arthritis can result by spread from an adjacent bone infection, direct contamination of the joint space through trauma or surgery, or hematogenous dissemination. Hematogenous spread of the disease comprises the majority of infections; spread from osteomyelitis and direct inoculation are much less frequent. Septic arthritis is most prevalent in children and the elderly. Approximately, one-third of people with septic arthritis are children younger than 2 years of age.[8]

Unlike children, adults often have significant systemic diseases that predispose them to septic arthritis, such as diabetes mellitus, immunosuppressive states (eg, cancer or liver disease), or preexisting joint disease, particularly rheumatoid arthritis. Additional risk factors associated with adult septic arthritis (more than one factor may be present) are systemic corticosteroid use, arthrocentesis, distant infection, or trauma. People who inject drugs (PWID) and individuals with intravascular infections such as endocarditis also are prone to develop septic arthritis.

PATHOPHYSIOLOGY

Osteomyelitis

Hematogenous Osteomyelitis

Hematogenous osteomyelitis is typically a disease of the growing bone in children, but occurs primarily in vertebrae of adults. Table 141-1 summarizes the primary characteristics of osteomyelitis.

TABLE 141-1

Types of Osteomyelitis, Age Distribution, Common Sites, and Risk Factors

Type of Osteomyelitis	Typical Age (years)	Site(s) Involved	Risk Factors
Hematogenous	<1	Long bones and joints	Prematurity, umbilical or other central venous catheter or venous cut-down, respiratory distress syndrome, and perinatal asphyxia
	1-20	Long bones (femur, tibia, and humerus)	Infection (pharyngitis, cellulitis, and respiratory infections), trauma, and sickle cell disease
	Older than 50	Vertebrae	Diabetes mellitus, blunt trauma to spine, and urinary tract infection
Contiguous	Older than 50	Femur, tibia, and mandible	Hip fractures and open fractures, soft tissue infections or abscesses
Direct Inoculation	<18	Feet and hands	Puncture injury to extremity or other trauma
Vascular insufficiency	Older than 50	Feet and toes	Diabetes mellitus, peripheral vascular disease, and pressure sores

Unique features of the anatomy and vascular supply of long bones appear to predispose them to become infected.[14] Bacteria are seeded within the metaphysis (Fig. 141-1) as the nutrient arteries of the long bones divide within the medullary canal of the bone into small arterioles. These end in hairpin turns near the growth plate and flow into veins, of much wider diameter, that drain the medullary cavity.[1] The infection is initiated within the bend of the arterioles where there is considerable slowing of blood flow in the hairpin capillary loops. This sludging of blood flow allows bacteria present within the bloodstream to settle and initiate an inflammatory response. They have access to the bone by gaps in the endothelium and the absence of a basement membrane. In addition to these structural features, phagocytosis is less active within the metaphysis. After the bacteria settle in the bone, avascular necrosis can occur from occlusion of the nutrient vessels and release of bacterial enzymes. Once the infection is initiated, exudate begins to form within the bone marrow and the fluid accumulates under increased pressure. The age of the patient largely determines the next stage in the pathophysiology.

FIGURE 141-1

Cross-section of normal bone.

Neonatal infections commonly involve multiple bones. The vascular supply of long bones in neonates has unique anatomic characteristics that affect their clinical presentation. Bridging blood vessels go across the epiphyseal plate from the metaphysis into the epiphysis, thus enabling an infection that started within the metaphyseal area to spread easily to involve the epiphyses and then break into the joint. Therefore, in infants, not only can the infection spread under the periosteum or break through the periosteum and the shaft as in older children, but the infection also can spread directly through the bridging blood vessels to involve the joint.

In children older than 12 to 18 months, hematogenous osteomyelitis typically involves a single bone and has a predilection for involvement of the long bones, such as the femur, tibia, humerus, and fibula. The infection that started in the metaphysis of a long bone is prevented from spreading into the epiphysis and the adjacent joint space because of the epiphyseal growth plate which acts as a physical barrier; however, the exudate often dissects from the medulla through the soft cortex to the subperiosteal space as the periosteum in these children is loosely attached to the underlying cortex. The periosteum is thick and not easily ruptured; thus, the subperiosteal space retains the pus, sometimes forming a subperiosteal abscess. If there is significant damage to the periosteum, the pus can decompress into a soft tissue abscess. The cortex obtains most of its blood supply from the periosteum and a subperiosteal abscess can impair the blood flow to the outer portion of the cortical bone resulting in a devitalized piece of dead bone termed a *sequestrum*. The elevated periosteum remains viable because its blood supply, derived from the overlying muscle, is unaffected. The raised periosteum will continue to produce bone; however, this new bone is now separated from the cortex because the periosteum has been raised from the infection. This new bone that is deposited under the periosteum is termed *involucrum*. In addition to these anatomic and functional features, there is some evidence that trauma is associated with developing an infection in specific bones. Children who develop hematogenous osteomyelitis may report some type of trauma before the onset of their symptoms, and animal data indicate that traumatized bone is more likely to become infected than normal bone.

In adults, the periosteum is tightly bound to the cortex which is thick. These anatomic features generally cause the infections to remain intramedullary. As expected, subperiosteal abscess formation is less common in this population. The infection can spread to subperiosteal structures through the Haversian and Volkmann canals.

Osteomyelitis of the vertebrae is also acquired hematogenously and this occurs most frequently in patients older than 50 years of age.[5] Vertebral disease in younger adults and children usually involves the disk space and the two vertebral facets adjoining it because of the nature of the vascular supply of the vertebrae at that age. This syndrome is known as diskitis.

Direct Inoculation Osteomyelitis

This category of osteomyelitis includes infections caused by direct entrance of organisms from a source outside the body. Penetrating wounds (eg, trauma), open fractures, and various invasive orthopedic procedures can result in direct inoculation of organisms into the bone. More than 80% of cases of postoperative osteomyelitis are known to occur following open reduction of fractures. Specifically, these infections occur most commonly after internal fixation of a hip, femoral, or tibial shaft fracture. Inoculation osteomyelitis can also occur as a result of penetrating foreign bodies, most commonly nail puncture injuries to the foot.

Contiguous Spread Osteomyelitis

Osteomyelitis secondary to spread from an adjacent soft tissue infection is called contiguous osteomyelitis. It can result from pressure ulcers (typically from laying in the decubitus position) or from adjacent soft tissue infections that most often involves the distal extremities (eg, diabetic foot infection). Less commonly, infections can spread from infected teeth to involve the mandible, or occur secondary to sinus infections by spreading through the mucosal lining of the sinuses into the vascular system surrounding the bone.

Contiguous-spread osteomyelitis occurs most commonly in patients older than age 50, likely because predisposing factors, such as diabetes mellitus, vascular diseases, or hip fractures, exist more often in this age group.

Patients with osteomyelitis in association with severe vascular insufficiency are extremely difficult to manage.[15] Frequently, patients with vascular disease develop osteomyelitis in their toes or even their fingers, and there is typically an adjacent area of infection, such as cellulitis or dermal ulcers. Importantly, infections in these patients can be polymicrobial, usually including *Staphylococcus* and *Streptococcus*, or a combination of those and Enterobacterales. Enterococci and anaerobic organisms also can be involved, but not as often.

Chronic Osteomyelitis

Chronic osteomyelitis is more likely to occur if large segments of bone become avascular and necrotic. It is common in inadequately managed foot infections of patients with diabetes. This results in a piece of devitalized bone to which antimicrobial delivery is impaired. As a result, the infection is prone to exacerbations and may lead to weakening of that bone or to the formation of draining sinuses to the skin.

Infectious Arthritis

Infectious arthritis usually is acquired by hematogenous spread. The synovial tissue is highly vascular and does not have a basement membrane, so organisms in the blood can easily reach the synovial fluid. Table 141-2 summarizes the characteristics of acute infectious arthritis.

TABLE 141-2

Characteristics of Acute Infectious Arthritis

Feature	Finding
Peak incidence	Children younger than 16 years Adults older than 50 years
Clinical findings	Fever of 38-40°C (100.4-104°F) in children; painful swollen joint in the absence of trauma Physical examination: Effusion, restriction of joint motion, tenderness, redness, and warmth of joint
Most commonly affected joints	Knee, hip, ankle, elbow, wrist, and shoulder
Laboratory findings	
Erythrocyte sedimentation rate	Elevated in 90% of cases
White blood cell count	Elevated in 30%-60% of cases
Left shift	Seen in two-thirds of patients
Blood culture	Positive in 40% of cases
Needle aspiration of joint	Gram-stain diagnostic in 30%-50% of cases. Synovial fluid cultures are positive in 60%-80% of cases. Synovial fluid yields an elevated white blood cell count with a high percentage of neutrophils. Synovial fluid glucose decreased relative to serum glucose. Lactic acid levels elevated in nongonococcal infectious arthritis, but not in gonococcal infectious arthritis

Preexisting abnormal joint architecture, joint trauma, and surgery are risk factors because chronic inflammation or trauma makes the joint more susceptible to infection. Individuals with rheumatoid arthritis can be prone to bacterial infection because of an inherent phagocytic defect, as well as concomitant corticosteroid therapy, biologic response modifier or other immunosuppressants. Patients infected with disseminated or untreated *N. gonorrhoeae* are at risk of gonococcal arthritis.

In addition to hematogenous spread, organisms can gain access to the joint from a deep-penetrating wound injury, intra-articular steroid injections, arthroscopy, prosthetic joint surgery, or spread to the joint from a contiguous focus of osteomyelitis. After bacteria gain access to the joint, the organisms begin to multiply and produce a purulent exudate within the joint. If this joint effusion is present beyond 7 days, chronic, and sometimes irreversible, damage can occur to the bone and joint as a result of proteolytic enzymes and pressure necrosis. Purulent effusions can promote cartilage destruction by increasing leukocyte enzyme activity. In conjunction with the development of the effusion, almost all patients will develop a hot, swollen, and painful joint.

CLINICAL PRESENTATION

Osteomyelitis

The clinical presentation of acute hematogenous osteomyelitis is summarized in Table 141-3. Although neonatal hematogenous osteomyelitis can spread rapidly to involve the joint, often there are few associated systemic symptoms.[14] A joint effusion is present in 60% to 70% of neonatal infections.

Decreased limb motion or edema over the affected area may be the only signs from which to suspect the diagnosis. While it is sometimes acute in onset, the disease is often insidious in children.

Vertebral osteomyelitis produces nonspecific symptoms, such as constant back pain, fever or night sweats, and weight loss.[5] The pain typically is present at rest and increases in severity with movement. Serious neurologic complications can occur if the infection extends and compresses the spinal cord.

The presentation of osteomyelitis after surgery or trauma depends on the precipitating cause. If the infection follows surgery or bone trauma, the symptoms usually are noted within 1 month. The most frequent symptom is pain in the area of infection. Less commonly, patients also can develop a fever and elevated WBC count.

With contiguous-spread osteomyelitis there is often an area of localized tenderness, warmth, edema, and erythema over the infected site. Patients with significant vascular insufficiency usually have local symptoms, such as pain, swelling, and redness. Less commonly, they also can have fever and elevated WBC count.

Infectious Arthritis

Patients with nongonococcal bacterial arthritis almost always present with a fever, and 50% of patients have an elevated WBC count (see Table 141-2). Nongonococcal bacterial arthritis is almost always monoarticular. The knee is the most commonly involved joint, but infections also can occur in the shoulder, wrist, hip, ankle, interphalangeal joints, and elbow joints. Sometimes, the initial focus of infection that acted as the portal of entry can be identified. Common routes for bacterial entrance include infections of the respiratory tract, skin, and urinary tract or which led to subsequent bacteremia; often no specific source can be identified. Blood cultures are important in these patients because they can be positive in 50% of patients.

The most frequent initial sign of disseminated gonococcal infections is the triad of dermatitis, tenosynovitis (inflammation and swelling of a tendon), and migratory polyarthralgia or polyarthritis. Women are more prone to develop disseminated gonococcal infections than men by a ratio of 4:1. The second and third trimesters of pregnancy and the time of menses appear to be the times of greatest risk for developing gonococcal bacteremia, hypothesized to be associated with mucosal vascularity. Common joints involved include the knee, wrist, elbow, and ankle. Presentation varies slightly depending on whether or not the woman is pregnant. In nonpregnant women, duration of symptoms are longer, presence of joint effusion is more likely, and white blood cells are more often present within the synovial fluid.[16]

Another type of infectious arthritis occurs following prosthetic joint surgery. The most common symptom is pain. Local signs of inflammation and fever are common in acute infections but chronic infections present in a more subtle fashion, typically with pain alone and often loosening of the prosthesis. With these infections, the C-reactive protein typically is elevated, although a leukocytosis often is absent. Infections from intraoperative contamination usually become apparent within 1 year of surgery. Those that present early (<3 months) are usually *S. aureus,* but occasionally gram-negative, anaerobic, or polymicrobial infections are also seen. Less virulent skin organisms such as *S. epidermidis, Enterococcus*, or the anaerobic gram-positive bacillus, *Cutibacterium* (formerly *Propionibacterium*) *acnes* present later, often 3 to 12 months from surgery. After 1 year, hematogenous spread becomes a risk factor for *S. aureus* infection again.

Radiologic and Laboratory Tests

Osteomyelitis

② The evaluation of a patient who may have osteomyelitis has several unusual aspects. Radiographs of the involved area should be obtained to rule out other processes such as a fracture. Bone changes characteristic of osteomyelitis appear late and are not typically seen until at least 10 to 14 days after the onset of the infection, as more than 50% of the bone matrix must be decalcified before the lesions can be detected radiologically. Magnetic resonance imaging (MRI) is the most sensitive and commonly used diagnostic imaging modality in those without metal hardware. It offers the advantage of better anatomic definition, especially of abscesses or joint effusions, compared to plain radiograph or traditional computed topography (CT) scan. Radionuclide bone scanning (with technetium or gallium) CT or positron emission tomography (PET) scanning can be useful in identifying the focus of osteomyelitis in patients unable to have an MRI.[17]

Despite the seriousness of osteomyelitis, often there are few laboratory abnormalities. The erythrocyte sedimentation rate (ESR), C-reactive protein, and WBC count may be the only laboratory abnormalities. The degree of abnormality of these laboratory findings does not correlate with the disease outcome; however, these inflammatory markers are useful for monitoring therapy. C-reactive protein is generally the more sensitive marker of response to therapy and often increases and decreases before the ESR.

When a clinical assessment of osteomyelitis is suspected, it is important to establish a bacteriologic diagnosis by culture of the infected bone and blood. Accurate culture information is especially important as a guide for treatment of osteomyelitis in this era of increasing antimicrobial resistance. Bone aspiration or bone biopsy is valuable in determining an accurate bacteriologic diagnosis. In addition, they help determine whether or not there is an abscess present. If an abscess is identified, it must be drained and the pus cultured with a Gram stain performed. Aspirates of subperiosteal pus or metaphyseal fluid yield a pathogen in 70% of cases. Cultures should be done for both aerobic and anaerobic bacteria. A Gram-stain result from the aspirate can be useful in initiating appropriate empirical antibiotic therapy.

If a specimen is obtained from a previously undrained or unopened wound abscess, the true etiologic pathogen usually can be identified. In chronic osteomyelitis, however, identification can be more difficult. Open wounds and draining sinuses frequently are contaminated with colonizing organisms and thus provide inaccurate culture information. They cannot be relied on to reflect the true etiologic pathogen unless consecutive deep sinus tract cultures reveal the same pathogens.[15] Cultures of loculated pus aspirates in the area of orthopedic devices removed from infected bone can be trusted, however, to identify the true etiologic organism. The preferable time to obtain culture material in a patient with a chronic draining sinus is at the time of open surgical debridement.

In addition to performing cultures from the involved bone, it also is important to obtain cultures from any site believed to be the primary source of a bacteremia. Approximately 50% of patients with hematogenous osteomyelitis will have positive blood cultures and may obviate the need for bone aspiration in these patients.

Infectious Arthritis

③Radiographs of infected joints often reveal distension of the joint capsule with soft tissue swelling in the adjacent space. MRI can be helpful in identifying an infected joint, especially the shoulder and hip. In patients who have developed an infected prosthetic joint, loosening of the prosthesis can be seen radiographically.

When evaluating the possibility of a patient having infectious arthritis, immediate joint aspiration with analysis of the synovial fluid is extremely important. The presence of purulent fluid usually indicates the presence of a septic joint, although other inflammatory arthritic conditions such as rheumatoid arthritis or gout can also demonstrate purulence. The synovial fluid WBC count and percentage of neutrophils found are important factors in defining an infectious etiology. The specific values best predictive of infection are variable based on multiple factors, including whether a native or prosthetic joint is being sampled, and exist along a continuum of sensitivity and specificity, as illustrated in Table 141-4. As with osteomyelitis, most patients will have an elevated C-reactive protein concentration and ESR. However, serum WBC, ESR, and C-reactive protein may not be useful acutely in septic arthritis.[18] Approximately half of patients with an infected native joint have a low synovial glucose level, usually less than 40 mg/dL (2.2 mmol/L). Both blood and joint fluid should be cultured aerobically and anaerobically in a patient suspected of having an infected joint. These cultures or Gram stains of joint fluid demonstrate bacteria in > 50% of patients with septic arthritis; however, such results are positive in only 25% of patients with gonococcal arthritis. Pharyngeal, rectal, cervical, or urethral smears and cultures, as well as cultures of cutaneous lesions, should be performed if a disseminated gonococcal infection is considered. Nucleic acid–based assays should also be used for the diagnosis of genital gonococcal infection.

TABLE 141-3

Clinical Presentation of Hematogenous Osteomyelitis

Signs and symptoms Significant tenderness of the affected area, pain, swelling, fever, chills, decreased motion, and malaise
Laboratory tests Elevated erythrocyte sedimentation rate, C-reactive protein, and white blood cell count 50% of patients will have positive blood cultures
Diagnostic studies Bone changes observed on radiographs 10-14 days after the onset of infection. Magnetic resonance imaging and technetium scans positive as early as 1 day after the onset of infection

TABLE 141-4

Synovial Fluid Analysis Associated with Infectious Arthritis

Native Joint Fluid	
WBC >50,000 cells/μL (50 x 10^9/L) >90% (0.90) neutrophil count	Sensitivity 62%, Specificity 92%, Sensitivity 73%, Specificity 79%.
Prosthetic Joint Fluid	
Knee	
Acute (<6 weeks from arthroplasty) WBC >8100 cells/μL (8.1 x 10^9/L) *Chronic (>6 months from arthroplasty)*WBC >1700 cells/μL (1.7 x 10^9/L) OR >65% (0.65) neutrophil count	Sensitivity 86%, Specificity 89%, Sensitivity ≈95%, Specificity ≈90%.
Hip	
WBC >4200 cells/μL (4.2 x 10^9/L)	Sensitivity 84%, Specificity 93%.

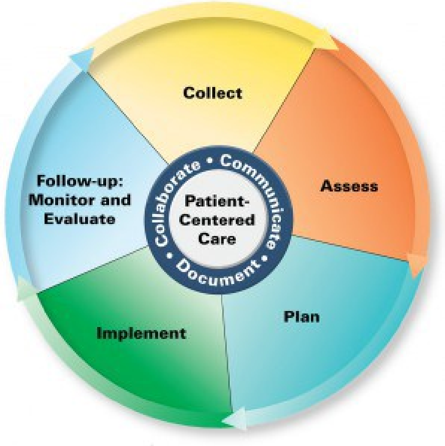
PATIENT CARE PROCESS

Patient Care Process for Bone and Joint Infections



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex, pregnancy status)
- Patient medical history
- Social history (eg, ethanol or illicit drug use) and living conditions
- Current medications and recent antibiotic use
- Objective data
    - Culture of bone, synovial fluid, or deep tissue (not superficial)
    - Labs including white blood cells (WBC), serum creatinine (SCr), and C-reactive protein (CRP) or erythrocyte sedimentation rate (ESR)
    - Imaging for infection

Assess

- Risk factors for bone and joint infections (Table 141-1)
- Markers of infection (Tables 141-2 and 141-3)
- Culture results and antimicrobial susceptibilities
- Ability/willingness to adhere to treatment regimen, including self-administration of outpatient parenteral therapy or travel to infusion center
- Ability/willingness to pay for treatment options (eg, home health, infusion center visits, and/or prescriptions from pharmacy)
- Ability/willingness to obtain laboratory monitoring tests (eg, WBC, SCr, serum drug concentrations)
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Drug therapy regimen including specific antibiotic dose, route, frequency, and duration (see Table 141-6)
- Monitoring parameters including efficacy (eg, WBC, CRP or ESR, pain, limb swelling) and safety (eg, complete blood count, SCr, diarrhea); frequency and timing of follow-up (Table 141-7)
- Patient education (eg, purpose of treatment, invasive procedures, drug-specific information, medication administration/injection technique)

- Self-monitoring for resolution of symptoms, occurrence of adverse effects, when to seek emergency medical attention
- Referrals to other providers when appropriate (eg, infectious diseases specialist, orthopedic surgeon, vascular surgeon, endocrine/diabetes specialist)

Implement*

- Provide patient education regarding all elements of treatment plan
- Use motivational interviewing and coaching strategies to maximize adherence
- Schedule follow-up (2-4 weeks)

Follow-up: Monitor and Evaluate

- Resolution of symptoms (eg, pain, limb/joint swelling, instability)
- Presence of adverse effects (eg, cytopenias, diarrhea, hypersensitivity reactions)
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate again at the end of therapy

**Collaborate with patient, caregivers, and other healthcare professionals.*

TREATMENT

Desired Outcome

Osteomyelitis

The goals of treatment are resolution of the infection and prevention of long-term sequelae. The ultimate outcome of osteomyelitis depends on the acute or chronic nature of the disease and how rapidly appropriate therapy including surgical drainage where appropriate is initiated. Patients with acute osteomyelitis have the best prognosis. Cure rates exceeding 80% can be expected for patients with acute osteomyelitis who have surgery when indicated and receive appropriate antibiotics for 4 to 6 weeks. When the growth plate is involved in children, discrepancies in the growth of bones or angular bone deformities can result. The infection is almost never fatal.

In contrast, patients with chronic osteomyelitis have a much poorer prognosis. Dead bone and other necrotic material from the infection act as a bacterial reservoir and make the infection very difficult to eliminate. Adequate surgical debridement to remove all the dead bone and necrotic material, combined with prolonged administration of antibiotics, provides the best chance to obtain a cure. The inability to remove all the dead bone can allow residual infection and require suppressive antibiotics to control the infection. Amputation, declines in quality of life, and recurrent infection are not uncommon with chronic osteomyelitis.

Infectious Arthritis

While many patients who develop infectious arthritis recover with no long-term sequelae, 50% are left with decreased joint function or mobility. Gonococcal arthritis usually resolves rapidly with antibiotics and has fewer sequelae. Individuals at greatest risk for long-term sequelae are those who have symptoms present for more than 7 days before starting therapy and those with infections occurring within the hip joint and infections caused by gram-negative organisms. Common long-term residual effects following infectious arthritis are limited joint motion and persistent pain.

During the initial phase of the infection, weight bearing such as walking on the joint should be avoided. Passive range-of-motion exercises should be initiated when the pain begins to subside to maintain joint mobility. Approximately one-third of patients with bacterial arthritis have a poor joint outcome, such as severe functional deterioration. Poor joint outcomes are associated with older patients, those with preexisting joint disease, and patients with an infected joint containing synthetic material.

General Approach to Treatment

Osteomyelitis

④ Following completion of the steps needed to determine the infecting organism, the most important treatment modality of acute osteomyelitis is the administration of appropriate antibiotics in adequate doses for a sufficient length of time. It is important to stress that early antibiotic therapy can mitigate the need for surgery, subsequent sepsis, chronic infection, disruption of longitudinal bone growth, and angular deformity of the bone. A long delay in treatment can allow bone necrosis to occur and make eradication of the infection much more difficult. In these patients with chronic osteomyelitis, exacerbations of the infection can result if all necrotic tissue or infected indwelling hardware are not removed surgically and all microorganisms eliminated. Chronic suppressive antimicrobial therapy and adjunctive treatment with hyperbaric oxygen or antibiotic-impregnated implants during surgery also have been used.

If a patient with hematogenous osteomyelitis does not respond by having a decrease in fever, local swelling, redness, and pain following the initiation of adequate antibiotic therapy, the patient should undergo surgical debridement of the infected area. It is important to emphasize the priority of starting antibiotics immediately after the cultures have been obtained for best microbiological yield and outcomes.[19]

Infectious Arthritis

Patients with infectious arthritis are typically admitted to the hospital to obtain synovial fluid and blood cultures and initiate antimicrobial therapy. An attempt to decrease bacterial burden in the joint space is made by performing either open or arthroscopic debridement. Empiric antibiotics are started as soon as culture specimens are collected. As with osteomyelitis, early initiation of antibiotic therapy is important to avoid complications such as avascular necrosis, limb-length discrepancy, and pathologic fractures. Staphylococci and streptococci are the most common organisms found in septic arthritis, accounting for approximately 70% to 85% of all cases, so treatment should be accordingly.[20,21]

In patients with prosthetic joint devices, orthopedic surgeons must work alongside infectious disease practitioners to determine the best course of action.[22] The gold standard treatment method includes resection of the implant, placement of a temporary antibiotic-impregnated cement spacer, and delayed component reimplantation. Retention of the implant may be necessary in patients who will receive irrigation and debridement in addition to antibiotic therapy, or antibiotic therapy alone in patients unable to tolerate surgical procedures.[23]

Pharmacologic Therapy

Osteomyelitis

Antibiotic Selection

A critical component in the management of osteomyelitis is the selection of appropriate antibiotics. Empiric therapy must be selected on the basis of the most likely infecting organism while the results of culture and susceptibility data are pending. Once culture and susceptibility results are obtained, the antimicrobial therapy should be tailored. Table 141-5 summarizes empiric therapy recommendations.

TABLE 141-5

Empiric Treatment of Osteomyelitis

Patient Subtype	Likely Infecting Organism	Antibiotic[a]	Recommendation Grades[b]
Newborn	*Staphylococcus aureus*, Group B *Streptococci, Escherichia coli*	Cefazolin 50-150 mg/kg/day IV	B-3
Children 3 years of age or younger	1. If vaccinated for *Haemophilus influenzae* type b: *K. kingae, S. aureus* or Streptococci 2. If not vaccinated against *H. influenzae* type b (*or Streptococcus pneumoniae)*	1. Cefazolin 100-150 mg/kg/day IV 2. Cefuroxime 150 mg/kg/day IV Alternatives are ceftriaxone 75 mg/kg/day IV or amoxicillin-clavulanate 40-45 mg/kg/day orally	B-3 B-3
Children 4 years of age and older	*S. aureus*	Vancomycin 60 mg/kg/day IV, clindamycin 40 mg/kg/day, or cefazolin 100-150 mg/kg/day IV	A-3
Adults	*S. aureus*	Vancomycin 15 mg/kg every 12 hours or cefazolin 2 g IV every 8 hours	A-3
IV drug users	*S. aureus, Pseudomonas*	Vancomycin 15 mg/kg every 12 hours plus ciprofloxacin 750 mg orally twice daily, ceftazidime or cefepime 2 g IV every 8 hours	B-3
Postoperative or posttrauma patients	Gram-positive and gram-negative organisms	Vancomycin 15 mg/kg IV every 12 hours plus ceftazidime or cefepime 2 g IV every 8 hours	B-3
Patients with vascular insufficiency	Gram-positive and gram-negative organisms	Vancomycin 15 mg/kg IV every 12 hours plus ceftriaxone 2 g every 24 hours	B-3
	If anaerobes suspected (necrosis)	Add metronidazole 500 mg every 8 hours or clindamycin 900 mg IV every 8 hours or substitute ertapenem for ceftriaxone	C-3

IV, intravenous.

[a] Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

[b] Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation, respectively. Quality of evidence: 1 = Evidence from more than one properly randomized, controlled studies or multiple time series; or dramatic results from uncontrolled experiments. 2 = Evidence from more than one well-designed clinical trial with randomization, from cohort or case-controlled analytic studies. 3 = Evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert communities.

With *Staphylococcus* being the most common bacteria in osteomyelitis, resistance patterns must be considered when deciding on an empiric agent. For communities showing low evidence of resistant strains of *S. aureus*, oxacillin or nafcillin has historically been the drug of choice, although cefazolin is now being used more often to treat susceptible strains due to ease of dosing, lower cost, and fewer adverse effects compared to anti-staphylococcal penicillins.[22-24] Clindamycin can be used in less severe cases, in patients with severe beta-lactam allergies or where methicillin-resistant

Staphylococcus aureus (MRSA) rates are unknown.[25,26] Clindamycin is used more commonly in children because MRSA is more likely to be community-acquired and susceptible to clindamycin in this population. If 10% or more of *S. aureus* isolates are methicillin resistant in the surrounding community, then an agent active against MRSA should be selected empirically. Vancomycin is the treatment of choice in this scenario and in adults since they often have risk factors for hospital-associated MRSA.[25,26] Daptomycin is an effective alternate in patients where mitigation of the adverse effects associated with vancomycin or a more convenient dosing strategy are prioritized.[27]

In the setting of vertebral osteomyelitis, empiric therapy should be initiated in conjunction with culture if the patient is hemodynamically unstable, septic, or experiencing neurologic compromise; otherwise, it is recommended empiric therapy be held while awaiting culture results.[5] Vancomycin in combination with a fluoroquinolone or third/fourth-generation cephalosporin such as ceftriaxone is a reasonable empiric regimen.

Antibiotic Bone Concentration

⑤ Antibiotics used in the management of acute osteomyelitis generally are given in high doses (adjusted for weight, renal function, hepatic function, or both) so that adequate antimicrobial concentrations are reached within the infected bone and joint.[23,28] Table 141-6 summarizes antibiotics doses that have been successful in the treatment of osteomyelitis.

TABLE 141-6

Antimicrobial Agents and Typical Doses for the Treatment of Bone and Joint Infections

Antimicrobial	Dose[a]	Comments
Amoxicillin	Adult: 1 g orally every 8 hours Children: 80-90 mg/kg/day divided every 12 hours	500-875 mg orally twice daily to 500 mg three times daily may be used for chronic suppression in adults
Amoxicillin/Clavulanate	Adult: 2,000/125 mg orally every 12 hours Children: 80-90 mg/kg/day of amoxicillin divided every 12 hours	875/125 mg orally twice daily or 500/125 mg three times daily may be used for step-down therapy or chronic suppression
Ampicillin	Adult: 2 g IV every 4 hours[21] Children: 150-200 mg/kg/day in four equal doses (max 8-12 g daily) VO: 12 g IV every 24 hours, continuous, or in six divided doses	May add IV aminoglycoside or ceftriaxone when treating *Enterococcus* spp. Continue adjunct therapy for 4-6 weeks in patients with infective endocarditis
Ampicillin/Sulbactam	Adult: 3 g IV every	3-g dose equals 2-g ampicillin and 1-g sulbactam

	6 hours	
Anti-staphylococcal penicillins (nafcillin, oxacillin, dicloxacillin)	Adult: Nafcillin or oxacillin 1-2 g IV every 4-6 hours Children: ≤200 mg/kg/day in four equal doses (max dose 8-12 g daily) VO: Nafcillin or oxacillin 1.5-2 g IV every 4-6 hours or continuous infusion	Adverse effects and cost are higher than cefazolin Dicloxacillin 500 mg three or four times daily may be used for suppression in adults
Aztreonam	Adult: 2 g IV every 8 hours	Use for patients with severe penicillin allergy and quinolone-resistant strains
Cefepime	Adult: 2 g IV every 8-12 hours	For Enterobacterales, 2 g IV every 12 hours
Cefotetan	Adult: 2 g IV every 12 hours	
Ceftazidime	Adult: 2 g IV every 8 hours	
Ceftriaxone	Adult: 2 g IV every 24 hours Children: 80-100 mg/kg/dose every 12-24 hours	
Ciprofloxacin	Adult: 400 IV every 8-12 hours or 500-750 mg orally every 12 hours	Should not be used as monotherapy for *Staphylococcus* infection, but may be combined with rifampin. Higher dose for *Pseudomonas*
Clindamycin	Adult: 600 mg IV every 6 hours or 300-600 mg orally every 6 hours Children: 40 mg/kg/day in four equal doses (max dose 3 g daily)	Recommended as second line for sensitive staphylococcal infection. 300 mg twice daily or three times daily may be used for suppression in adults

	VO: 600-900 mg IV every 8 hours, or 300-450 mg orally four times daily	
Daptomycin	Adult: 6-8 mg/kg IV every 24 hours	
Doxycycline	Adult: 100 mg orally twice daily	Can be used in addition to rifampin for Brucella infection
Ertapenem	Adult: 1 g IV every 24 hours Children: 15 mg/kg every 12 hours	
First-generation cephalosporin (Cefazolin, Cephalexin)	Adult: Cefazolin 2 g IV every 8 hours Children: 100-150 mg/kg/day in 3 equal doses (max dose 6 g daily)	Cephalexin 500 mg orally every 6 hours or 1 g orally every 8 hours for step-down treatment.[21] Cephalexin 500 mg twice or three times daily may be used for suppression
Imipenem/cilastatin	Adult: 500 mg IV every 6 hours	Can add IV aminoglycoside empirically for treatment of *P. aeruginosa*
Levofloxacin	Adult: 500-750 mg IV once daily or 750 mg orally once daily	Add rifampin for treatment of *S. aureus*
Linezolid	Adult: 600 mg IV or orally every 12 hours Children: 30 mg/kg/day in three equal doses (max dose 1.2 g for no more than 28 days)	Long-term use can lead to cytopenias
Meropenem	Adult: 1 g IV every 8 hours	
Metronidazole	Adult: 500 mg orally or IV every 8	Drug of choice for *Bacteroides* species and other susceptible anaerobes

	hours	
Minocycline	Adult: 200 mg orally initially, then 100 mg orally twice daily	
Moxifloxacin	Adult: 400 mg orally once daily	For streptococci, enterobacteriaceae, and other susceptible gram-negative organisms. Not recommended for staphylococcal infection unless combined with rifampin
Penicillin G	Adult: 3-4 million units IV every 4 hours or 20 million units IV continuous every 24 hours	For *Enterococcus*, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis
Piperacillin/Tazobactam	Adult: 4.5 g IV every 6-8 hours	Every 6 hours or extended infusion (over 4 hours) for *P. aeruginosa*
Rifampin	Adult: 300 mg orally twice daily Children: 10 mg/kg/day orally divided twice daily	Only to be used in combination with another antimicrobial
Trimethoprim–Sulfamethoxazole	Adult: 1-2 double-strength tablets orally twice daily hours or 1 double-strength tablet orally three times a day	Second-line agent for Enterobacteriaceae and other susceptible aerobic gram-negative organisms. May need to monitor sulfamethoxazole levels[5]
Vancomycin	Adult: 15 mg/kg IV every 12 hours Children: 60 mg/kg/day in four equal doses	Adjust based on patient and pharmacokinetic parameters. Target trough of 15 mcg per milliliter (mg/L; 10.4 μmol/L) or area under the concentration-curve of 400-600. Consider loading dose for MRSA and *Enterococcus*. For *Enterococcus*, add 4-6 weeks of aminoglycoside therapy in patients with infective endocarditis. Use only if bacteria is known . Use only if resistant to beta-lactams or patient is allergic to first-line options

IV, intravenous; MRSA, methicillin resistant *Staphylococcus aureus*; VO, vertebral osteomyelitis.

[a] Dosage should be adjusted for some agents in patients with renal and/or hepatic dysfunction.

Oral Antibiotic Therapy

6 Criteria for the use of oral outpatient antibiotic therapy for osteomyelitis include all of the following:

- Confirmed osteomyelitis
- Initial positive clinical response to parenteral antibiotics
- A suitable oral agent is available
- Adherence is ensured

Suitable candidates are children with good clinical response to intravenous therapy and adults without diabetes mellitus or peripheral vascular disease.

The use of oral antibiotics is well studied in children.[29–31] Typically, injectable antibiotics are used initially and then switched to oral antibiotics when the patient is afebrile and there is a decrease in the signs of inflammation.[19] If pus is obtained on the initial needle aspirate, or if a reduction in fever, local swelling, and tenderness does not occur despite adequate rest, immobilization, and intensive antibiotic therapy, patients undergo surgical drainage. The patients enrolled in oral antibiotic trials generally had disease of recent onset, identification of a specific infecting organism, enforced adherence, and surgery as indicated. In patients who meet these criteria, oral antibiotics appear to offer a great advantage in the treatment of osteomyelitis. Patients not meeting these criteria may have a higher risk of developing chronic osteomyelitis if oral therapy is inappropriate or not strictly adhered to. In adults, oral antibiotics are used more conservatively due to more limited blood flow to the bones but evidence is emerging that oral therapy can be effective for adult osteomyelitis and septic arthritis.[32–34] Ciprofloxacin and levofloxacin are well-studied oral primary therapy due to their high bioavailability and great distribution into bone.[35] Flouroquinolones (with the exception of delafloxacin) are not reliably effective against Staphylococci on their own as resistance develops rapidly and should not be used alone empirically. They have successfully been combined with rifampin when isolates are susceptible to both classes of drugs.[36] Rifampin is particularly useful for treating infections with biofilms that have a propensity to grow on smooth surfaces such as bone, and especially prosthetic devices.[37] However, rifampin has a multitude of drug interactions, and caution should be used when adding to a regimen.

Duration of Antibiotic Therapy

7 Following debridement, bone takes 3 to 4 weeks to revascularize, which becomes the basis of treatment duration. The specific duration of antibiotic therapy needed in the management of osteomyelitis and septic arthritis has traditionally been 4 to 6 weeks and 3 to 4 weeks, respectively.[38] For adults, those durations of treatment are still recommended but newer studies in children have explored shorter durations along with more liberal transitions to oral antibiotics. For children with *septic arthritis*, a course as short as 10 days is sufficient as long as the C-reactive protein level normalizes.[39] French guidelines recommend treatment for a minimum of 3 weeks in children with osteomyelitis as failure rates approaching 20% have been observed with antibiotics administered for less than that.[40] This is based on studies showing that improvement in the patient's clinical signs and symptoms in addition to normalization of the C-reactive protein level or ESR is an important parameter for predicting efficacy.[41,42] Treatment failures may be due to the presence of residual bacteria in necrotic bone or infected hardware (wires, plates, screws, and rods) that could not be removed.[35] If signs or symptoms are still present at the end of therapy, treatment should be extended. For adults, guidelines from the Infectious Diseases Society of America (IDSA) recommend therapy for 8 weeks in adults with osteomyelitis from MRSA,[43] particularly in patients with vertebral osteomyelitis at high risk of relapse such as those with end-stage renal disease or undrained paravertebral/psoas abscesses.[44] In some cases of chronic osteomyelitis, lifelong suppressive therapy might be the most appropriate option, particularly when prosthetic devices remain.[45] The goal in chronic suppressive therapy is to avoid readmissions from exacerbation of established infection; however, the use of this approach must be balanced with the risk for development of antimicrobial resistance and toxicity over extended periods.[46] Often specific dosing regimens of oral therapies are utilized in this situation (see Table 141-6).[46]

Duration of antibiotic administration for vertebral osteomyelitis can vary depending on the infecting organism, extent of bone destruction, or presence of abscesses. The IDSA guidelines recommend a minimum of 6 weeks of either parenteral therapy or highly bioavailable oral therapy.[3] This is necessary because of the outcomes in older patients with degenerative bone disease that have reduced blood flow to the site of infection and are most at risk of the disease. With gram-negative bacteria a longer duration (8 weeks or greater) is associated with less rates of recurrence compared to shorter durations (4-6 weeks).[7] One prospective trial compared 6 and 12 weeks of treatment for patients with pyogenic vertebral osteomyelitis (most commonly *S. aureus*) and found the longer duration to be no better.[47] However, patients with prosthetic joint infections have benefited from 12 weeks of antibiotic therapy.[48] For patients with retained hardware following prosthetic joint infection, 3 to 6 months of therapy is often necessary.[45] Many questions remain on the optimal duration for bone infections in adults and whether it is safe to use shorter courses.[35]

Special Populations

Osteomyelitis in the intravenous drug user has unique features. More than 50% of such infections involve the vertebral column and up to 20% of infections are located in either the sternoarticular or pelvic girdle. Infections are much less frequent within the extremities. They also have an unusual spectrum of organisms. Although *Staphylococcus* and *Streptococcus* are sometimes cultured, with MRSA being more common than the general population, gram-negative bacteria are responsible for many infections. In one outbreak *P. aeruginosa*, either singly or in combination with other organisms, was cultured in 78% of all such infections. *Klebsiella, Enterobacter*, and *Serratia* species also can be less commonly identified. Spinal infections are caused predominately by *S. aureus.*[49]

Patients with sickle cell anemia and related hemoglobinopathies also represent a unique population, in that two-thirds of bone infections in these patients are caused by *Salmonella* species, while the rest are usually caused by staphylococci and other gram-negative organisms.[50] Bowel infarctions from sickle cell disease can facilitate the entry of salmonellae from the colon into the bloodstream with resultant hematogenous spread to the bone. Osteomyelitis in patients with sickle cell disease may occur in any bone, but it most commonly involves the medullary cavity of long or tubular bones. Because of the difficulty in separating bone pain during a sickle cell crisis from that of an infection, osteomyelitis can be relatively advanced in these patients by the time the diagnosis is made.

Infectious Arthritis

Antibiotic Selection

⑧The three most important treatments for infectious arthritis are appropriate antibiotics, joint drainage, and joint rest. Smears of the synovial fluid can be useful to select appropriate antibiotic therapy initially.[8] If bacteria are not observed on the Gram stain in a patient who has a purulent joint effusion, antibiotics still should be initiated because of the low sensitivity of the Gram stain. A delay in initiating antibiotics significantly increases the likelihood for long-term complications. The specific antibiotic selected depends on the most likely infecting organism, but it should typically target *Staphylococcus* spp. (eg, vancomycin, daptomycin, or clindamycin). When staphylococci infect prosthetic hardware that cannot be removed, rifampin is recommended to be added to the therapy for its effects on biofilm, but drug–drug interactions should always be evaluated with use of this agent.[45]

Antibiotic Joint Space Concentration

The antibiotics selected usually are administered parenterally to achieve sufficient concentrations within the synovial fluid, and thus intra-articular antibiotic injections are unnecessary.

In prosthetic joint infections, antimicrobial cement spacers are often used to aid in delivery of the antimicrobial to the site of infection. The most common antimicrobials used include vancomycin and aminoglycosides (tobramycin or gentamicin).[51] However, the doses of each agent are widely variable and it is uncertain whether the placement of antimicrobial cement spacers adds outcome benefit to systemic therapy.[51,52] The idea that antimicrobial cement spacers provide only beneficial local exposure of the antimicrobial agent without systemic consequences has been questioned.[53] The incidence of acute kidney injury in patients receiving treatment with antimicrobial cement spacers was 4.8%, with the incidence ranging from 2% to 17% based on the definition of acute kidney injury used.[54]

Similar to osteomyelitis, once the infection is confirmed and initial response to parenteral therapy is achieved, culture susceptibilities have resulted, and adherence is ensured, then selected oral antibiotics can be used for the treatment of infectious arthritis.

Home Antibiotic Therapy

Because the management of bone and joint infections frequently requires prolonged parenteral antibiotics, administration of intravenous treatment in the home or a clinic is commonly performed. This is called outpatient parenteral antimicrobial therapy (OPAT). Although acute osteomyelitis is one of the more common infectious diseases that can be treated with long-term intravenous antibiotics outside the hospital, not all patients are acceptable candidates for home administration. Patients must be screened to include those who are receiving a stable treatment, are interested and motivated in participating, who have good venous access, often have support from family members or caregivers, and safe and stable housing including refrigerated drug storage capability. Certain exclusion criteria also must be considered. Patients are not eligible if their eyesight or dexterity prevent them from attaching the admixture to their catheter when they do not have a caregiver that can help them daily. Although many providers are leery about allowing patients to receive parenteral antibiotics at home if they have any recent history of intravenous drug use, this bias is inappropriate in the setting of a structured therapy program for opioid use disorder which can lead to better outcomes for both disease states.[56] In addition to meeting these initial screening criteria, patients complete training before hospital discharge. Understanding of aseptic technique, proper catheter care, and correct administration techniques must be documented. Complications in patients receiving outpatient courses of parenteral antibiotics are fairly common (18%), and often lead to readmission when they occur.[57,58] Patients without adequate insurance or the support at home necessary to administer intravenous antibiotics may choose to come to an infusion center for each treatment. Others may need to be admitted to a skilled nursing facility for the duration of their therapy. A midline or central intravenous catheter is often required for long-term venous access. This is most commonly accomplished with a peripherally inserted central catheter (PICC).

The specific antibiotic regimen characteristics must also be considered when evaluating a patient for home antibiotics. After susceptibility of the microbiologic culture, the number of required daily antimicrobial doses is important. Most skilled nursing facilities are only able to accommodate infusions once each day. The stability of the antibiotic at room temperature is relevant when considering a continuous infusion (that can ideally be exchanged once daily), and shelf life can determine the required frequency of deliveries. Aminoglycosides and vancomycin have unique requirements for monitoring of the regimen, such as more frequent serum creatinine and drug-level monitoring. Although an organism can be susceptible to several antimicrobial agents, the use of the most practically simple regimen may often take precedence in OPAT over antimicrobial stewardship principles of selecting the most narrow spectrum agent.[58]

Individualized Therapy

Individualized therapy is important in the treatment of osteomyelitis and infectious arthritis. Patient quality of life may be significantly diminished in the short term from an inconvenient treatment regimen, but the long-term sequelae of inadequately treated infection can be much worse, such as impaired joint motion-draining sinus tracts, or even amputation, if it is required. Patient demographics, infection characteristics (eg, infecting organism and its susceptibility patterns), treatment cost, and quality-of-life issues all play a major role in evaluating individualized treatment alternatives (oral therapy or OPAT) rather than requiring patients to remain hospitalized to receive 4 to 6 weeks of intravenous antibiotics. Although serious adverse reactions are uncommon, in one study 85.7% of children receiving vancomycin had some form of adverse drug events and 42.9% of patients required the drug be discontinued.[59] Monitoring is important to ensure that personalized therapy is effective to both cure the infection and minimize the risk for complications.

EVALUATION OF THERAPEUTIC OUTCOMES

Monitoring of the Pharmaceutical Care Plan

⑨ Patients with bone and joint infections must be monitored closely. Table 141-7 summarizes a pharmaceutical care monitoring protocol. An assessment of a therapy's success or failure is based on the patient's clinical findings and laboratory values. The clinical signs of inflammation, such as swelling, tenderness, pain, redness, and fever, should resolve relatively quickly with appropriate therapy. Initially, the clinical signs are assessed daily until improvement and then periodically thereafter. Elevations in the C-reactive protein or ESR may not return to normal until after several weeks of therapy. The WBC count usually is obtained once (or twice) per week until it returns to the normal range and then is monitored for myelosuppression along with other blood cells. If by the end of the 4- to 6-week antibiotic course the clinical findings of osteomyelitis are no longer present and the C-reactive protein and ESR are within normal limits, the patient can be considered a clinical cure. Patients can relapse, however, after initially appearing to be cured. No relapse for 1 year generally is considered a complete cure.

TABLE 141-7

Monitoring Protocol

Parameter	Frequency	Notes
Culture and susceptibility	At initiation of treatment	No need to repeat unless clinical failure or original was not from a deep culture site (surgical sample)
Basic or complete metabolic laboratory panel	Weekly	Monitoring for electrolyte abnormalities and renal function
C-reactive protein or erythrocyte sedimentation rate	At initiation and completion of treatment	Although some providers will obtain weekly, this is often unnecessary as levels may not normalize until several weeks of therapy are complete
Therapeutic drug monitoring	Weekly	Agents such as vancomycin, aminoglycosides, and some antifungal therapies require ongoing monitoring for efficacy, toxicity, or both.
Clinical signs of inflammation (redness, pain, swelling, tenderness, and fever)	Daily during initiation of therapy	
Adherence of outpatient therapy	Reinforce before starting therapy and with each healthcare visit	Adherence is critical if treatment is to be successful
Complete blood count	Weekly	White blood cell count is monitored for normalization to indicate efficacy. Certain antimicrobial agents may cause blood dyscrasias when used for long-term therapy (eg, linezolid, trimethoprim–sulfamethoxazole, even vancomycin and beta-lactams to a lesser extent)

If a patient fails to resolve the clinical signs and symptoms of inflammation after appropriate empirical antibiotics, suspicion for an abscess should be raised. Additional imaging and surgical debridement may be needed, particularly in situations where there was retained hardware or incompletely resected infection. In addition, the patient might have a resistant or an atypical infecting organism that may require a modification of the antibiotic therapy. It is especially important to identify the infecting organism and its susceptibility pattern. Follow-up cultures at subsequent debridements can be useful to assess the antibiotic therapy in patients with unresolved infection.

Despite apparently adequate surgery and antibiotics, some patients can fail therapy and have relapses in their infection. This scenario is more common in those having chronic osteomyelitis, especially with peripheral vascular disease. These patients can require long-term oral suppressive antimicrobial therapy to keep the infection under control.

ABBREVIATIONS

CRP	C-reactive protein
CT	computed tomography
ESR	erythrocyte sedimentation rate
IDSA	Infectious Diseases Society of America
MRI	magnetic resonance imaging
MRSA	methicillin-resistant *Staphylococcus aureus*
OPAT	outpatient parenteral antimicrobial therapy
PET	positron emission tomography
PICC	peripherally inserted central catheter
PWID	person who injects drugs
WBC	white blood cell
VO	vertebral osteomyelitis

SELF-ASSESSMENT QUESTIONS

1. What type of osteomyelitis occurs most commonly in children?

A. Chronic

B. Contiguous

C. Direct inoculation

D. Hematogenous

2. Infectious arthritis most commonly involves how many joints?

A. 1

B. 2

C. 3

D. 4

3. Which of these bacteria is most likely to cause a joint infection in a patient who had a prosthetic knee replacement 7 months ago?

A. *S. aureus*

B. *S. epidermidis*

C. *N. gonorrheae*

D. *K. kingae*

4. In a child known to have osteomyelitis from methicillin-susceptible *S. aureus,* what is the standard duration of antimicrobial therapy if they have responded adequately?

A. 1 week

B. 3 weeks

C. 6 weeks

D. 12 weeks

5. What is the most common organism causing hematogenous osteomyelitis?

A. *Group B Streptococcus*

B. *Haemophilus influenzae*

C. *Pseudomonas aeruginosa*

D. *Staphylococcus aureus*

6. Compared to other types of bone infections, which of these most accurately describes the pathogens that cause osteomyelitis in a patient with diabetic foot infection?

A. Anaerobic

B. Gram negative

C. Gram positive

   D. Multiple organisms

7. What is the most common organism causing adult bacterial arthritis?

   A. *E. coli*

   B. *P. aeruginosa*

   C. *S. aureus*

   D. *S. pyogenes*

8. What would be the most useful long-term monitoring strategy for a patient with osteomyelitis?

   A. C-reactive protein daily

   B. White blood count daily

   C. Erythrocyte sedimentation rate every 6 months

   D. C-reactive protein at the beginning and end of therapy

9. When used alone, oral ciprofloxacin for osteomyelitis would be most likely to fail with which infecting organism?

   A. *Serratia marcescens*

   B. *S. aureus*

   C. *Enterobacter cloacae*

   D. *E. coli*

10. Which antimicrobial regimen would be most appropriate for empiric treatment of hematogenous osteomyelitis in a 7-year-old boy?

   A. Ampicillin

   B. Cefuroxime

   C. Doxycycline

   D. Clindamycin

11. Which antimicrobial regimen would be most appropriate for empiric treatment of hematogenous osteomyelitis in an IV drug abuser?

   A. Levofloxacin

   B. Vancomycin and ceftazidime

   C. Nafcillin and cefepime

   D. Clindamycin

12. Which of these antimicrobial agents is most commonly used in cement spacers following prosthetic joint infection?

   A. Ampicillin

   B. Ceftriaxone

   C. Ciprofloxacin

D. Tobramycin

13. Which antimicrobial is most likely to cause thrombocytopenia if used for a prolonged time period?

A. Ampicillin

B. Ceftriaxone

C. Linezolid

D. Metronidazole

14. What location is most common for contiguous osteomyelitis to occur in adults?

A. Foot

B. Humerus

C. Mandible

D. Vertebrae

15. What duration of therapy is most appropriate for a patient with vertebral osteomyelitis caused by MRSA?

A. 2 weeks

B. 4 weeks

C. 8 weeks

D. 16 weeks

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Hematogenous osteomyelitis occurs most often in children. The source of infection likely comes from minor breaks in the skin or normal oral bacteria that enter into the bloodstream. Due to good blood flow to growing bones infection is usually curable and does not progress to chronic stage (A) Contiguous osteomyelitis (B) often comes from adjacent soft tissue infection which is more common in patients with diabetes. Direct inoculation (C) can result from surgery or trauma such as a motor vehicle accident that are rare overall.

2. **A.** Infectious (septic) arthritis most commonly inflicts only one joint. The exception is when hematogenous infection seeds multiple joints. This would be more common in patients with a continuous source such as infective endocarditis where the body is unable to eliminate the bacteria because of limited immune activity on heart valves where bacteria are attached in a protective biofilm-forming vegetation.

3. **B.** *Staphyloccocus epidermidis* is the most likely bacteria to cause prosthetic joint infection 6 to 12 months after surgery. Although it is not normally considered a pathogen because of being a nonvirulent skin commensal, it can contaminate prosthetic devices during surgery and cause an indolent infection. It is often not detected until many months after surgery and can sometimes present with signs such as joint loosening, which is not as indicative of infection. That is why it is very important to collect multiple cultures when exploring the joint to diagnosis infection. A single culture with *S. epidermidis* is difficult to assess as infection without more traditional symptoms. White blood cells in the synovial fluid or detected in tissue during surgery are the best way to determine if it is a potential causative organism. It is an organism that has a strong propensity to form biofilm on prosthetic surfaces and it can be very difficult to eradicate. *S. aureus* also has the ability to attach to foreign surfaces but is very aggressive and presents weeks to a few months after surgery if it is introduced into the wound during the operation. It causes more traditional signs of infection such as redness, pain, and swelling. Even a single colony of *S. aureus* detected is enough to warrant treatment. After 12 months, *S. aureus* can also infect the new joint following skin abrasions, even those that are not detected by the patient. *Neisseria gonorrheae* can cause septic arthritis in those that are young and sexually active but it is not a pathogen of concern following prosthetic joint infection. *K. kingae* is common in young children from 6 months to about 3

years old, but it is not seen in prosthetic joint infection.

4. **B.** Children have more vascular bones that means antibiotics and white blood cells can reach the site of infection better. Healing is typically much more rapid than in adults and relapse rates lower. Therefore, 3 to 4 weeks is the usual duration of therapy in children compared to 6 to 8 in older patients, especially when the pathogen is known and empiric antibiotic therapy was effective. Many European countries have a low rate of MRSA and guidelines recommend 3 weeks of therapy. The United States has higher MRSA rates and some practitioners might be hesitant to use short courses but children can also develop adverse effects of antibiotics prescribed for long periods. Although septic arthritis has been treated with 10 days of therapy, 1 week is too short for any bone or joint infection. Twelve weeks on the other hand is unnecessarily long in a typical patient.

5. **D.** *S. aureus* is the most common pathogen causing hematogenous osteomyelitis. It is an aggressive pathogen that has a tendency to spread from other areas of the body and seed locations such as the bones that are difficult for the immune system to eradicate. Group B *Streptococcus* can occur in neonates following birth to a mother that is positive for the organism, particularly when perinatal antibacterial prophylaxis was not properly administered. *Haemophilus influenzae* (B) still causes respiratory infection but type B that was responsible for invasive disease has been nearly eradicated from developed countries through the use of conjugate vaccine. *P. aeruginosa* (C) is rare but can be seen in patients who use unclean needles or tap water for injecting drugs or those with open fractures occurring outdoors, especially following contact with water.

6. **D.** Although gram-positive pathogens are still the most likely cause of osteomyelitis in patients with diabetes, the chance of having mixed infection of the foot is enhanced due to proximity with multiple organisms inside shoes and dirt. Also, the poor vasculature of many patients with diabetes means lack of oxygen that impairs wound healing and increases risk of anaerobic infection.

7. **C.** As with osteomyelitis, *S. aureus* is the most common organism to cause bacterial septic arthritis in adults. Gram negatives such as *E. coli* and *P. aeruginosa* are rare while *Streptococcus pyogenes* is more typical of neonates.

8. **D.** C-reactive protein is an acute inflammatory marker that can be used to help assess response to therapy in patients with bone infections. Some clinicians follow it weekly with other labs such as WBC and Scr. Most important is to compare the initial C-reactive protein value with the value at the expected end of therapy. This is the basis for when to choose a shorter length of therapy in children and helps reassure prescribers that therapy is adequate in adults. (A) Checking daily is not needed. (B) White blood cell count is often assessed daily for the initial part of infection to watch for resolution of leukocytosis but it typically normalizes in a few days, making prolonged daily checks unnecessary. Continued monitoring is more useful to assess for cytotoxic effects from the antibacterials and this can be accomplished with weekly monitoring.(C) Erythrocyte sedimentation rate is another nonspecific inflammatory marker like CRP, but it usually takes longer to increase and decrease. Sometimes it never becomes positive if infection is detected early. When positive, monitoring is often done with CRP but an argument could be made that only one or the other needs to be checked. Waiting 6 months, however, is not likely to be useful.

9. **B.** Ciprofloxacin should not be used alone for *S. aureus*. This is because fluoroquinolones have a propensity for a single-stage mutation that leads to not only resistance of the class but also beta-lactams, converting *S. aureus* into MRSA (perhaps with the exception of delafloxacin, which is still new but is reported to be much more stable to resistance). Fluoroquinolones have quite a bit of data for the treatment of *S. aureus* in combination with rifampin, another class of antibiotic that should not be used alone for therapy. *Serratia marcescens* and *Enterobacter cloacae* are good choices to treat with fluoroquinolones because both can possess an inducible beta-lactamase called ampC that makes cure with other traditional agents, such as ceftriaxone, more difficult. Although resistance in *E. coli* (and *P. aeruginosa*) has increased to 25% to 30% in most areas of the United States, fluoroquinolones are still effective choice for susceptible gram-negative bone infections.

10. **D.** Due to high rates of MRSA (>30% in most parts of the United States), clindamycin is the only treatment from the list that can be recommended empirically. Vancomycin would be an alternative. In parts of Europe, MSSA is much more common and cefuroxime could be chosen, although nafcillin, cefazolin, or other equivalents (oxacillin, flucloxacillin) would more likely be used. Cefuroxime would also be effective against *K. kingae* which is more common in younger preschool children. Clindamycin is a well-studied treatment in pediatrics and popular because most community-acquired MRSA remains susceptible. Ampicillin is a drug of choice for *Enterococcus faecalis* and could be used for streptococcal infection, but is not recommended empirically for osteomyelitis. Doxycycline is considered an effective treatment for *S. aureus* but not recommended in children due to potential staining of bones and teeth.

11. **B.** IV drug abuser have a higher rate of MRSA infection than the general population and have a propensity for infection with gram-negative infections, especially *P. aeruginosa*. Therefore, combination therapy is commonly employed to provide empiric treatment for both. Vancomycin is effective for MRSA while ceftazidime retains good activity against *P. aeruginosa*. None of the other choices are reliable against both pathogens. Once

the infective organisms have been identified it is always advisable to de-escalate therapy to a more narrow, targeted spectrum of activity.

12. **D.** Tobramycin is often used in bone cement because aminoglycosides have attractive concentration-dependent pharmacodynamics that can be enhanced with high doses at the site of surgery. Despite this theoretical benefit, little data exist on their actual contribution to improvement in clinical care and there remains a documented risk of systemic absorption resulting in toxicity such as acute kidney injury. Beta-lactams have time-dependent effects and are occasionally used locally, while fluoroquinolones are very rarely used in cement.

13. **C.** Linezolid has a propensity to cause thrombocytopenia when used for more than 1 to 2 weeks. That is why linezolid is typically not chosen to treat bone or even joint infections despite it having excellent activity against MRSA and adequate concentrations present in bone. While beta-lactams such as ampicillin and ceftriaxone can also cause cytopenias and cell counts should be monitored on therapy, the adverse event is much less common. Metronidazole can be associated with dysgeusia and peripheral neuropathies, especially during prolonged use, but most experts do not exclude it as a treatment for anaerobic osteomyelitis.

14. **A.** Contiguous osteomyelitis occurs from adjacent soft tissue infection. This is much more likely to occur in the foot due to the propensity of wounds in that area of the body to track all the way to the bone. This is common in patients with diabetes who have neuropathy and do not initially recognize the seriousness of their injury and subsequent foot infection. The mandible is another area of the body prone to contiguous osteomyelitis, but the occurrence of dental infection is much less in general. The humerus is unlikely to become infected except by direct inoculation from trauma or potentially hematogenous spread. The source of vertebral osteomyelitis is almost always from hematogenous infection but can be associated with adjacent diskitis or epidural abscess.

15. **C.** Eight weeks is the recommended treatment duration for MRSA vertebral osteomyelitis because it is considered an infection at high risk of relapse. By default, vertebral osteomyelitis occurs in adults who have less robust blood supply to their bones, and bacteria have a propensity to find degenerated areas in the spine to develop infection. This and the less than ideal pharmacologic agents used to treat MRSA infection lead patients to require a longer course of therapy than might be necessary for children and even other types of osteomyelitis in adults. Two and 4 weeks are too short, while 16 weeks is not likely to improve outcomes but puts patients at increased risk of adverse drug events.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 142: Sepsis and Septic Shock

S. Lena Kang-Birken; Sul R. Jung

KEY CONCEPTS

KEY CONCEPTS

① Gram-negative organisms are isolated in 44% to 59% in sepsis or septic shock, followed by gram-positive bacteria in 37% to 52%, and fungi in 4% to 10%. *Candida albicans* remains the most prevalent *Candida* species: however, non-*albicans Candida* species collectively is more frequently isolated.

② Pathogenesis of sepsis is complex and multifactorial consisting of causative pathogen, host characteristics, and the inflammatory responses during which the interactions between pro- and anti-inflammatory cytokines, procoagulant state, and decreased fibrinolysis occur simultaneously.

③ The highest mortality is reported in patients with complicated intra-abdominal infections, chronic kidney disease, renal replacement therapy, multiple organ dysfunction, candidemia, and septic shock.

④ Initial resuscitation from sepsis-induced hypoperfusion should begin with at least 30 mL/kg of IV crystalloid fluid. Dynamic fluid responsiveness assessment by examining cardiac output with fluid bolus is essential to avoid fluid overload.

⑤ Prompt initiation of empiric broad-spectrum intravenous (IV) antibiotics within 1 hour of recognition of sepsis or septic shock improves survival, and the regimen should be assessed daily for potential de-escalation.

⑥ Norepinephrine is the preferred vasopressor in fluid-resuscitation refractory septic shock, and vasopressin may be added to achieve and maintain mean arterial pressure (MAP) goal of at least 65 mm Hg.

⑦ Implementation of a performance improvement program encompassing sepsis screening for high-risk patients and immediate treatment including fluid resuscitation, antimicrobial agents, treatment includes echinocandins, triazoles, or a formulation of amphotericin B and faster transition to vasopressor to meet MAP goal improves patient outcomes.

⑧ Intravenous hydrocortisone is recommended for patients with septic shock who require ongoing norepinephrine to maintain target MAP.

⑨ Initiate insulin therapy at a glucose level of greater than 180 mg/dL (10 mmol/L) with a target range between 144 and 180 mg/dL (8-10 mmol/L) to reduce potential hypoglycemia and associated mortality.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “Four Ways to Get Ahead of Sepsis” by the Centers for Disease Control and Prevention (CDC), https://www.youtube.com/watch?v=5JvGiAFLels. This 2-minute video provides an overview of manifestation of sepsis especially among individuals who are at high risk of infection. It highlights the importance of prevention, recognition of the signs and symptoms of sepsis, and awareness of sepsis as medical emergency. This video will enhance the students’ understanding regarding the COLLECT and ASSESS steps in the patient care process. In a small group, create your own treatment summary pocket card for sepsis and septic shock based on the 2021 Surviving Sepsis Campaign international guidelines. Name the preferred initial treatment regimen and monitoring plan for the following: fluid resuscitation, antimicrobial therapy, vasopressor, and adjunct therapy including glucose control, corticosteroid, venous thromboembolism prophylaxis and stress ulcer prophylaxis. This activity will enhance the student understanding of key treatment elements of the PLAN step in the patient care process.

INTRODUCTION

Sepsis is a medical emergency when left untreated has a high probability of death. It has a unique disease process where it may impact multiple organ systems. The inflammatory response with the release of numerous cytokines will directly affect the vasculature causing a capillary leak, hypovolemia, decreased cardiac output, and hypotension leading to renal failure, heart failure, brain failure, also puts stress on our endocrine system, etc. Due to the potential expansive downward spiral, sepsis requires a prompt recognition, efficient assessment, and aggressive treatment.

DEFINITIONS

The recent sepsis guidelines published in 2016 (Sepsis-3) derived new categorization and definition of the sepsis continuum.[1] However, it is still important to recognize the old definitions related to the spectrum of sepsis and how they were utilized in the clinical trials and guidelines prior to the 2016 revision. Periods of bacteremia, systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, septic shock, or multiple organ dysfunction syndrome often overlap, and they signify an important continuum of progressive physiologic decline. *Severe sepsis* was defined in patients with an acute organ dysfunction, such as acute renal failure or respiratory failure in 2012 guidelines (Sepsis-2).[2] Sepsis-induced hypotension is defined as a systolic BP less than 90 mm Hg or MAP less than 70 mm Hg (Table 142-1).[2] *Septic shock* refers to sepsis patients with sepsis-induced hypotension that is refractory to adequate fluid resuscitation, thus requiring vasopressor administration. Sepsis-induced tissue hypoperfusion is defined as infection-induced hypotension, elevated lactate, or oliguria.[2,3] Sepsis-3 redefined sepsis by combining sepsis and severe sepsis from Sepsis-2 guideline as “life-threatening organ dysfunction caused by a dysregulated host response to infection.”[1] The definition of septic shock is when a septic patient has persistent hypotension (MAP < 65 mm Hg) requiring vasopressor along with continued elevated serum lactate (≥18 mg/dL [2 mmol/L]) post adequate fluid resuscitation defined as 30 mL/kg of crystalloids.

TABLE 142-1

Comparison of Definitions from Sepsis-2 and Sepsis-3 Guidelines

Sepsis-2 Guideline (2012)	**Sepsis-3 Guideline (2016)**
Systemic inflammatory response syndrome (SIRS) to infectious or noninfectious insults: Two or more of the following: • Temperature >38°C or <36°C • Heart rate >90 beats/minute • Respiratory rate >20 breaths/minute • WBC >12,000/mm^3 (12 x 10^9/L) or <4,000 cells/mm^3 (4 x 10^9/L) or > 10% (0.10) immature bands **Sepsis**: SIRS + probable or documented infection **Severe sepsis**: Sepsis + one or more organ dysfunction or hypoperfusion **Septic shock**: Sepsis + refractory hypotension despite fluid resuscitation (30 mL/kg) or serum lactate >9 mg/dL (1 mmol/L)	**Sepsis**: Life-threatening organ dysfunction caused by a dysregulated host response to infection • Acute change in total SOFA score ≥2 points **Septic shock**: Sepsis + persistent hypotension requiring vasopressor use and serum lactate >18 mg/dL (2 mmol/L) despite adequate fluid resuscitation

SOFA, sequential organ failure assessment; WBC, white blood cell.

Data from References 1,2.

EPIDEMIOLOGY

Sepsis continues to pose a major healthcare burden. The US Nationwide Inpatient Sample reported a significant increase in the hospitalizations due to sepsis from 1.2% in 2005 to 2.7% in 2014.[4] Despite aggressive, prompt medical care and advances, overall in-hospital deaths remain approximately 15%, but the mortality rate may be as high as 50.7% in septic shock.[4–6] In addition, the total cost of hospitalization due to sepsis increased from $22.2 to $38.1 billion between 2005 and 2014, making it the most expensive condition to be treated in US hospitals.[4] Given the public health and financial burden, there is a vital need for clinicians to comprehend the pathophysiology and optimal management approaches for acutely ill patients with sepsis or septic shock.

ETIOLOGY

Risk Factors for Infection

Pathogenesis of sepsis is multifactorial, which begins with the patient's specific predisposition to infection. Advanced or young age, pre-existing conditions including heart failure, diabetes, chronic obstructive pulmonary disease, cirrhosis, alcohol dependence, end-stage renal disease, and other immunosuppressive diseases such as neoplasm and human immunodeficiency virus (HIV) predispose patients at risk for infection.[4,7] Male sex has been associated with a higher incidence of sepsis in prior studies; however, the difference between the sexes is diminishing.[7,8] Once the infection occurs, the risk factors for developing sepsis and organ dysfunction have not been well described. However, multiple factors including patients' risk factors for infection, site of infection, etiologic microorganism, and a specific organ dysfunction as well as the number of organs contribute to poor prognosis.[7,9]

Pathogens

① Among the microorganisms isolated from blood cultures, gram-negative organisms were isolated in 44% to 59% of patients with sepsis or septic shock, gram-positive bacteria in 37% to 52%, anaerobic organisms in 5%, and fungi in 4% to 10%.[8–12] However, in the majority (approximately 70%) of sepsis cases, a specific causal microorganism was not documented.[8,10]

The most common anatomic source of infection that leads to sepsis is the lung (40%-42%), followed by intra-abdominal space (31%-34%) and genitourinary tract (11%-15%).[9–11]

Gram-Negative Bacteria

Escherichia coli is by far the most commonly isolated gram-negative microorganism in sepsis (55%-60%), followed by *Klebsiella* species, *Proteus* species, *Enterobacter* species, and *Pseudomonas aeruginosa*.[9,11,13,14] *P. aeruginosa* and *Acinetobacter* species are more likely to be associated with prior antibiotic exposure and usually exhibit multidrug resistance.[14,15]

Mortality increases significantly with increasing severity of sepsis (3.5% for sepsis, 9.9% in severe sepsis, and 29% in septic shock), especially in the presence of *P. aeruginosa*.[14] Furthermore, the severity of underlying conditions is a major factor associated with the negative outcome of gram-negative sepsis. For example, patients with rapidly fatal conditions, such as acute leukemia, aplastic anemia, cirrhosis, or HIV, have a significantly worse prognosis than those patients with nonfatal underlying conditions such as diabetes mellitus or chronic renal insufficiency.[7]

Gram-Positive Bacteria

The most common gram-positive organisms are *Staphylococcus aureus*, followed by coagulase-negative *Staphylococci*, *Enterococcus* species, and *Streptococcus pneumoniae*.[9,11,13] Higher mortality in S. aureus bacteremia was reported in older age, shock, preexisting renal failure, and the presence of a rapidly fatal underlying disease. Enterococci are most commonly isolated from blood cultures following a prolonged hospitalization and treatment with broad-spectrum cephalosporins.

Anaerobic Bacteria

Anaerobic bacteria, most commonly *Bacteroides fragilis* and *Clostridium* species, are usually considered low-risk organisms for the development of sepsis. If present, anaerobes are often found together with other pathogenic bacteria that are commonly found in sepsis. Polymicrobial infections accounted for 5% to 39% of sepsis, especially in cases of intra-abdominal infections.[7,11,13] Mortality rates associated with polymicrobial infections are similar to sepsis caused by a single organism.

Fungi

Candidemia is among the most common fungal etiologic causes of bloodstream infections. *Candida albicans* remains the most prevalent *Candida* species from blood isolates (38%-61%), but there are increasing incidences of invasive infections due to non-*albicans* species.[9,12,16–18] Non-*albicans Candida* species include *C. glabrata* (16%-28%), *C. parapsilosis* (14%-17%), *C. tropicalis* (7.5%-17%), and *C. krusei* (4.1%). Traditionally, risk factors for fungal infection include abdominal surgery, poorly controlled diabetes mellitus, prolonged granulocytopenia, use of broad-spectrum antibiotics or corticosteroids, prolonged hospitalization, central venous catheter, total parenteral nutrition, hematologic malignancy, and chronic indwelling bladder (Foley) catheter. Patients with candidemia and severe sepsis and septic shock were more likely to have been admitted from nursing homes or transferred from outside hospitals.[12]

The use of azoles in response to the rising incidences of *Candida* bloodstream infection has led to fluconazole-resistant *Candida* species. Resistance to fluconazole occurs in 17% of *C. albicans*, 58% of *C. parapsilosis*, 33% of *C. glabrata*, and 100% of *C. krusei* among critically ill patients with invasive candidiasis.[17]

Patients with septic shock due to candidemia had a 30-day mortality rate of 54%. A higher in-hospital mortality of 61% was reported among patients with healthcare-associated candidemia. The mortality rate was 53% in patients with *C. krusei* candidemia; *C. parapsilosis* candidemia was associated with the lowest 12-week mortality rate of 24%.[19]

PATHOPHYSIOLOGY

② The cascade leading to the development of sepsis is complex and multifactorial, involving causative pathogen (virulence and organism load), host characteristics (comorbidities and immunosuppression), and the inflammatory responses (Fig. 142-1). The inflammatory responses lead to damage to host tissue, and the anti-inflammatory response causes leukocytes to activate. If the balance to control the local inflammatory process and to eradicate the invading pathogens is lost, systemic inflammatory response occurs which may lead to sepsis and septic shock.

Cellular Components for Initiating the Inflammatory Process

The pathophysiologic focus of gram-negative sepsis has been on the lipopolysaccharide component of the gram-negative bacterial outer cell membrane. Commonly referred to as endotoxin, this substance is generally released with bacterial lysis. Upon its release, it forms a complex with an endogenous protein called a lipopolysaccharide-binding protein. Lipid A is the innermost region of the lipopolysaccharide and is highly immunoreactive. Its predominant effect is to activate macrophages through the CD14 receptor located on the macrophage. This endotoxin-lipopolysaccharide–binding protein complex is responsible for most of the toxic effects—the release of cytokine mediators which triggers the inflammatory cascade that is critical in the progression to sepsis and/or septic shock.[20]

In gram-positive sepsis, the exotoxin peptidoglycan on the cell wall surface exhibits pro-inflammatory activity. Similar to lipid A component of gram-negative bacteria, the exotoxin peptidoglycan binds to the CD14 receptors of the macrophages. However, the potency of exotoxin peptidoglycan is less than that of endotoxin.[20] Clinically important exotoxins are those produced by *S. aureus* and *Streptococcus pyogenes* in septic shock.

Pro- and Anti-Inflammatory Mediators

A complex interaction between pro-inflammatory and anti-inflammatory mediators plays a major role in the pathogenesis of sepsis. In general, pro-inflammatory reactions are directed at eliminating invading pathogens and the anti-inflammatory reactions limit local and systemic tissue injury. The key pro-inflammatory mediators are tumor necrosis factor (TNF) and interleukin (IL)-1, IL-6, and IL-12, which are released by activated macrophages and endothelial cells. The TNF level is highly elevated early in the inflammatory response in the majority of patients with sepsis, which leads to activation of other cytokines such as IL-1 and IL-6, associated with cellular damage. There is a correlation between the plasma TNF levels and the severity of sepsis and poor prognosis. In addition, higher levels of IL-6 have been reported in patients with septic shock than in those with SIRS.[21] TNF also stimulates the release of cyclooxygenase-derived arachidonic acid metabolites (thromboxane A_2 and prostaglandins) that contribute to vascular endothelial damage.

The significant anti-inflammatory mediators include interleukin-1 receptor antagonist (IL-1RA) IL-4, and IL-10. IL-1RA binds to IL-1, blocking its activity. Furthermore, anti-inflammatory cytokines inhibit the production of the pro-inflammatory cytokines and down-regulate some inflammatory cells. Levels of IL-10 and IL-1RA are higher in septic shock than in sepsis, and higher levels are found among nonsurviving patients than in survivor.[21,22]

The activation and secretion of pro- and anti-inflammatory mediators in septic shock occur as a simultaneous immune response as early as the first 24 hours of diagnosis, but the balance between pro- and anti-inflammatory mechanisms determines the degree of inflammation, ranging from local antibacterial activity to systemic tissue toxicity, organ failure, shock, or death (Fig. 142-1).

Cascade of Sepsis

Macrophages and endothelial cells produce a variety of cytokines that mediate a primary mechanism of injury in sepsis. When injured, endothelial cells allow circulating cells such as granulocytes and plasma constituents to enter inflamed tissues, which can result in organ damage.

The microcirculation is also affected by sepsis-induced inflammation. The arterioles become less responsive to either vasoconstrictors or vasodilators. The capillaries are less perfused even at the early phases of septic shock, and there is neutrophil infiltration and protein leakage into the venules.[23]

The inflammatory process in sepsis is also directly linked to the coagulation system. Pro-inflammatory mechanisms that promote sepsis are also procoagulant and antifibrinolytic, whereas fibrinolytic mechanisms can be anti-inflammatory.[24] A key endogenous substance involved in inflammation of sepsis is activated protein C, which enhances fibrinolysis and inhibits inflammation. Levels of protein C are generally reduced in patients with sepsis.[24]

COMPLICATIONS

Sepsis may lead to several complications including disseminated intravascular coagulation (DIC) and multiple organ dysfunctions, which are important predictors of patient outcome. Among the patients admitted to US hospitals between 2009 and 2014 due to sepsis, approximately half had at least two acute organ dysfunctions.[5] National inpatient data between 2005 and 2014 reported approximately 20% of patients with sepsis having three-organ dysfunction, and an increase in the proportion of patients having four or more organ dysfunction from 16% to 24%.[4] The organ dysfunction occurred most frequently in kidneys (39%-49%), lungs (24%-43%), and heart (28%-40%).[4,5,8,25,26] Septic shock is the most ominous complication associated with sepsis. Among the patients who presented to the emergency department with sepsis, 3.6% progressed to septic shock within the first 4 hours, and 8.4% progressed to septic shock between 4 and 48 hours.[27] The predictors for progression to septic shock in the latter group included female gender, nonpersistent hypotension, band neutrophils of at least 10% (0.1) in blood, lactate of at least 36 mg/dL (4 mmol/L), and past medical history of coronary artery disease.[27]

Disseminated Intravascular Coagulation

The host inflammatory response to infection is a protective mechanism against the infecting pathogen. However, it also triggers disturbances in coagulation. A dynamic process between procoagulant mechanisms and naturally occurring anticoagulants occurs nearly universally in septic patients.

The initial procoagulant state is the interaction between the pro-inflammatory cytokines, such as TNF, IL-1, and IL-6, tissue factor expression by endothelial cells and mononuclear phagocytes, and platelet-activating factor, which together contributes to hypercoagulopathy in the early inflammatory state.[28] Simultaneously, antithrombin synthesis is down-regulated, allowing ongoing thrombin formation. This acute phase interaction of the pro-inflammatory and hypercoagulative state is believed to sequester bacteria as part of compartmentalization.[28] Coagulation abnormalities consisting of excessive fibrin formation, compromised fibrin removal from a depressed fibrinolytic system, and endothelial injury may manifest as a small reduction in platelet count and subclinical clotting time prolongation or in more severe cases, DIC.

Simultaneous widespread microvascular thrombosis and profuse bleeding from various sites characterize DIC. Consumption of clotting factors from ongoing thrombosis eventually leads to a hypocoagulable state. Various degrees of coagulation abnormalities may be present in 50% to 70% of septic patients. However, about 35% will progress to DIC.[28] Complications of DIC vary and depend on the affected organ and the severity of the coagulopathy. DIC can produce acute renal failure, hemorrhagic necrosis of the gastrointestinal (GI) mucosa, liver failure, acute pancreatitis, acute respiratory distress syndrome (ARDS), and pulmonary failure. As the procoagulant state is the key to the ignition of the pathogenesis to DIC and multiple organ dysfunction, coagulation dysfunction and organ dysfunction often coexist in sepsis.

Acute Kidney Injury

The acute kidney injury (AKI), defined as an absolute increase in serum creatinine of 0.3 mg/dL (27 mmol/L) or more within a 48-hour period, not only affects survival but also leads to worsening of chronic kidney disease or failure requiring renal replacement therapy. Sepsis-induced AKI has been reported up to 49% and was associated with hypoperfusion, leading to renal ischemia. However, normal or even increased renal blood flow may be present in sepsis-induced AKI, providing an explanation for lack of beneficial evidence with the use of dopamine, a renal vasodilator in the treatment of AKI in septic patients. Rather, AKI develops from a complex relationship between the activation of inflammation and pro-inflammatory molecules causing renal tubular injury and tubular epithelial dysfunction.[29] Subsequently, the injured kidney is unable to regulate the blood flow, making it more vulnerable to changes in blood flow as BP varies and ultimately lead to progression to multiple organ dysfunction.

Acute Respiratory Distress Syndrome

ARDS is a serious and potentially fatal condition, characterized by severe hypoxemia that is resistant to oxygen. The National Inpatient Sample reported increased incidence of ARDS in the United States from 2006 to 2014, and sepsis is one of the most common risk factors (47%), followed by pneumonia (45%) and shock (44%). Moreover, sepsis-associated ARDS had a higher mortality rate in comparison to other risk factors.

ARDS involves multifactorial processes which begin with activated neutrophils and platelets adhering to the pulmonary capillary endothelium which then initiates multiple inflammatory cascades with a release of a variety of toxic substances. There is diffuse pulmonary endothelial cell injury, increased capillary permeability, and alveolar epithelial cell injury. Consequently, interstitial pulmonary edema occurs that gradually progresses to alveolar flooding and collapse. The end result is loss of functional alveolar volume, impaired pulmonary compliance, and profound hypoxemia.[30]

Abnormalities of coagulation and fibrinolysis are also integral to the pathogenesis of ARDS. Coagulation is locally upregulated in the injured lung, whereas fibrinolytic activity is depressed. These abnormalities occur concurrently, but favor alveolar fibrin deposition, leading to local inflammation, macrophage migration, and increased vascular permeability.

Hemodynamic Effects

Sepsis and septic shock are associated with excessive sympathetic outflow, high plasma catecholamine levels, myocardial depression, vascular hyporeactivity, and autonomic dysfunction. The hallmark of the hemodynamic effect of sepsis is the hyperdynamic state characterized by low systemic vascular resistance (SVR) and high cardiac output with tachycardia and arterial hypotension.[23,31]

Sepsis-induced myocardial dysfunction, defined as the intrinsic myocardial systolic and diastolic dysfunction of both the left and right sides of the heart, occurs from excessive adrenergic stress.[32] Sepsis from overwhelming inflammation may cause direct myocardial damage (eg, cardiomyopathy and tachyarrhythmia). Simultaneously, the heart, as part of the circulatory system responding to peripheral hemodynamics, may be responding to alterations in preload, afterload, and microcirculation during sepsis. The microvasculature system, consisting of arterioles, capillaries, venules, and microlymphatics, is a functional system that responds promptly to changes in blood flow to the tissues and metabolic demand. It regulates adequate blood flow to tissues, ensuring adequate oxygen delivery and meet the oxygen demand. During sepsis and septic shock, massive pro-inflammatory cytokines are released, targeting the endothelium, the key component of this microvascular blood flow. Consequently, microvascular impairment leads to loss of ability to regulate oxygen distribution within the capillary network.[23] The severity of microcirculatory abnormalities and their persistence are associated with organ dysfunction. The combination of decreased preload, reduced afterload, myocardial dysfunction, microcirculatory impairments, and blood flow redistribution between organs lead to hemodynamic alterations during sepsis.

Septic Shock

There are four different types of shock syndrome: hypovolemic, cardiogenic, obstructive, and vasodilatory/distributive. Septic shock falls under the vasodilatory/distributive shock. Distributive shock results from overall systemic vasodilation leading to hypoperfusion. Hallmark signs and symptoms of distributive shock include a decrease in BP, an increase in heart rate in response to a decrease in SVR, and pulmonary capillary wedge pressure. The cardiac output is typically normal after adequate fluid resuscitation in vasodilatory shock unlike other syndromes which are expected to have a low cardiac output. Details of the different shock syndromes are discussed in Chapter e42, "Shock Syndromes."

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Sepsis and Septic Shock

The clinical presentation of sepsis varies significantly depending on the site of the infection (ie, pulmonary versus urinary tract), host response to the infection based on the patient's underlying health status and risk factors, and organ dysfunction. The initial presentations may include general malaise or myalgia and nonspecific signs such as fever (or hypothermia), chills, tachycardia, tachypnea, or change in mental status. As uncontrolled sepsis progresses, the presentation varies again depending on the specific organ system dysfunction. Arterial hypotension can be present, which may compromise organ perfusion, leading to oliguria. Hyperventilation can occur, causing impaired gas exchange which can then lead to respiratory alkalosis. Altered glucose metabolism, including impaired gluconeogenesis and excessive insulin release, is evidenced by either hyperglycemia or hypoglycemia. Increased glycolysis with impaired clearance of lactate by the hypoperfused liver and kidneys result in elevated lactate levels which then contributes to metabolic acidosis.

Prognostic Factors

③ The highest mortality was reported in patients with intra-abdominal infection secondary to ischemic bowel (75%), whereas obstructive uropathy-associated urinary tract infection was associated with the lowest hospital mortality (26%).[10] In-hospital mortality rate with AKI in sepsis was two- to threefold higher in patients with stage 3 kidney disease compared to those without kidney disease. Furthermore, the mortality rate was significantly higher in patients receiving renal replacement therapy than those without (40% vs 22%, respectively).[33] Associated mortality rates were also high in patients with severe sepsis and ARDS and DIC (36% and 29%, respectively).[26] As the number of failing organs increased from one to four or more, the mortality rate increased from 15% to 40% (Fig. 142-2).[5] Patients with candidemia generally have septic shock, and the associated mortality is significantly higher in comparison to patients with bacteremia (47% vs 28%, respectively).[12]

FIGURE 142-2

Mortality related to the number of failing organs.

Copyright © McGraw Hill. All rights reserved.

An elevated serum lactate concentration of more than 36 mg/dL (4 mmol/L) upon initial presentation and persistent elevation in lactate for more than 24 hours were associated with an increased mortality rate.[34] Furthermore, the 28-day mortality rate was the highest (45%) among patients with septic shock and hyperlactatemia of more than 23 mg/dL (2.5 mmol/L), followed by hyperlactatemia without vasopressor need (35%), and no hyperlactatemia with vasopressor need (28%). Hyperlactatemia increased the risk of 28-day mortality independent of vasopressor need.[35]

Diagnosis

Identification of Pathogens

The presence of clinical features suggesting sepsis should prompt further evaluation of the patient. In addition to obtaining a careful history of any underlying conditions and recent travel, injury, animal exposure, infection, or use of antibiotics, a complete physical examination should be performed to determine the source of the infection.

A collection of specimens should be sent for culture prior to initiating any antimicrobial therapy to increase the yield of cultures, making identification of a pathogen more likely. Minimally, two sets of blood cultures (both aerobic and anaerobic bottles) should be collected without temporal separation between the sets.[2] Culturing of all body sites is not generally recommended, but the decision regarding which sites to culture requires careful consideration and should be based on the patient presentation and the likely site of infection. With suspected catheter-related infection, one set of blood cultures should be drawn through every lumen of each vascular access device along with peripheral blood cultures. In severe community-acquired pneumonia, respiratory secretions along with blood cultures must be obtained. Urinary antigen detection of *S. pneumoniae* and *Legionella* serogroup 1 is recommended to yield identification. To document a soft tissue infection, a Gram stain and bacterial culture of any obvious wound exudates should be performed. A needle aspiration of a closed infection such as cellulitis or abscess may be needed for Gram stain and bacterial culture. In abdominal infections, fluid collections identified by imaging studies should be aspirated for Gram stains and aerobic and anaerobic cultures. Implementation of accurate and rapid molecular diagnostic testing has demonstrated a positive impact on prescribing appropriate therapy in bloodstream infections such as methicillin-resistant *S. aureus* (MRSA) and *Candida* species.[2,36,37]

A lumbar puncture is indicated in altered mental status, severe headache, or a seizure, assuming there are no focal cranial lesions identified by computed tomography scan. Further tests may be indicated to assess any systemic organ dysfunction caused by severe sepsis. The laboratory tests should include WBC with differential, hemoglobin, platelet count, complete chemistry profile, coagulation parameters, serum lactate, and arterial blood gases. The potential role of biomarkers such as PCT levels or C-reactive protein for diagnosis of infection in patients with sepsis remains undefined as there is no definitive way to discriminate the acute inflammatory pattern of sepsis from other generalized inflammation.[2]

Assessment of Acutely Ill, High-Risk Patients

Sepsis-3 redefined sepsis to “life-threatening organ dysfunction caused by a dysregulated host response to infection” based on the evidence of greater in-hospital mortality among patients with sequential sepsis-related organ failure.[1,38] As such, early recognition of sepsis using a formal screening tool is critical. Organ dysfunction can be evaluated by using the SOFA scoring system. SOFA encompasses various organ systems such as pulmonary, coagulation, hepatic, cardiovascular, renal, and neurological and gives a score ranging from 0 to 4 for each system to characterize a septic patient's prognosis (Table 142-2). Higher total score is associated with an increased probability of mortality. A SOFA score of 2 or more is associated with an increased risk of mortality by 10% in hospitalized patients with presumed infection.[1] One of the difficulties in using the SOFA score is that clinicians need laboratory results such as platelets, bilirubin, and creatinine, which may not be available initially. Quick SOFA (qSOFA), on the other hand, utilizes three data elements: respiratory rate ≥22 breaths/min, altered mental status, and systolic BP ≤ 100 mm Hg. qSOFA of ≥2 or SOFA score change of ≥2 can serve as an indication for higher vigilance and potentially quicker escalation of care. If baseline SOFA score is unknown, then score of zero is used as baseline. If a patient has all three mentioned elements, in-hospital mortality can be as high as 40% to 50%.[1] However, the 2021 Surviving Sepsis Campaign guideline recommends that qSOFA should not be used as a single screen tool since it is less sensitive than having two of four SIRS criteria in identifying sepsis-induced organ dysfunction.[39]

TABLE 142-2

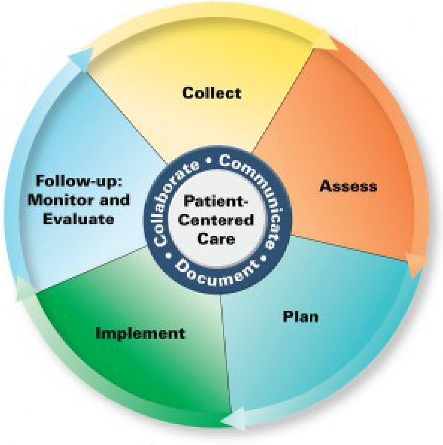
Abbreviated Sepsis-Related Sequential Organ Failure Assessment

Organ System	Measured Variables for Scoring System
Pulmonary	PaO_2/FiO_2 (<200 to ≥400 mm Hg [26.6-53.2 kPa])
Coagulation	Platelets (<50 to ≥ 150 × 10^3/mm^3 [50 × 10^9 -150 × 10^9/L])
Liver	Bilirubin (<1.2-11.9 mg/dL [20.5-203.5 µmol/L])
Cardiovascular	MAP (<70 with or without vasopressor to ≥70 mm Hg)
Central nervous system	Glasgow Coma Scale (6-15)
Renal	Serum creatinine (<1.2-4.9 mg/dL [106-433 µmol/L]), urine output (<500 mL/d)

FiO_2, fraction of inspired oxygen; MAP, mean arterial pressure; PaO_2, partial pressure of oxygen.

Data from Reference 1.

Patient Care Process for Sepsis and Septic Shock



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Collaborate • Communicate • Document •
Patient-Centered Care

Collect

- Patient characteristics (eg, age, sex)
- Patient medical history (including recent hospitalization and infection within last 6 months)
- Social history (eg, tobacco/ethanol use/intravenous drug user/place of residence)
- Current medications (prescription and nonprescription; including recent history of antibiotic usage within last 6 months)
- Subjective data (including general constitutional and infection-site specific, onset)
- Objective data
    - Temperature, blood pressure (BP), heart rate, respiratory rate, mean arterial pressure (MAP), O_2-saturation, height, and weight
    - Labs including white blood cell (WBC) count with differential, hemoglobin, platelet count, complete serum chemistry including serum creatinine, and bilirubin, lactate, procalcitonin (PCT), coagulation panel including prothrombin time and activated partial thromboplastin time, and arterial blood gas including pH, $PaCO_2$, PaO_2, and HCO_3
    - Objective parameters for sequential organ failure assessment (see sequential organ failure assessment [SOFA]; Table 142-2)
    - Microbiology data (including Gram stain, culture, rapid diagnostic testing)

Assess

- Mental status
- Systemic inflammatory response (SIRS) criteria (Table 142-1)
- Hemodynamic stability (eg, systolic BP> 100 mm Hg, MAP> 65 mm Hg)
- Presence of organ dysfunction (lactate > 18 mg/dL (2 mmol/L), baseline; SOFA/qSOFA; Table 142-2)
- Identification of pathogen and antibiotic susceptibility
- Risk of multidrug-resistant bacterial pathogen (recent hospitalization, infection, antibiotic-resistant organism, broad-spectrum antibiotic usage)
- Risk of fungal pathogen (recent usage of broad-spectrum antibiotics/corticosteroids/total parenteral nutrition, abdominal surgery, etc.)

Plan*

- Initiate 1-hour performance improvement bundle (Table 142-7)
- Initial fluid resuscitation with intravenous (IV) balanced crystalloid for hypotension
- Begin antimicrobial therapy regimen based on site of infection (Table 142-5)
- Perform passive leg raise to assess response to fluid resuscitation (increase in stroke volume by 10%-15%)
- Initiate vasopressor if MAP < 65 mm Hg with adequate fluid resuscitation (Table 142-6)
- Administer IV hydrocortisone if ongoing requirement for vasopressor to maintain MAP
- Initiate adjunct therapy including glucose control, venous thromboembolism prophylaxis, and stress ulcer prophylaxis
- Monitoring parameters: including efficacy (eg, signs and symptoms of infection, mental status, MAP, lactate, WBC with differential) and safety

Implement*

- Management of vasopressor selection after initial norepinephrine
- Daily assessment for opportunities to de-escalate antimicrobial therapy
- Design tapering schedule of IV hydrocortisone
- Coordination of treatment plan during transitioning from the ICU to a medicine unit

Follow-up: Monitor and Evaluate

- Resolution of symptoms of infection
- PCT levels along with clinical evaluation to determine the antimicrobial treatment duration
- Normalization of lactate and MAP > 65 mm Hg for discontinuation of vasopressors
- Presence of adverse effects of antimicrobial agents and vasopressors

[*] *Collaborate with other healthcare professionals.*

TREATMENT

Since publication of the Surviving Sepsis Campaign in 2003, key concepts have changed the way we recognize and treat septic patients over the decades.[40] In 2001, early goal-directed therapy (EGDT) with resuscitation targets was introduced, and it heavily influenced the Sepsis-2 guideline.[2,41] The 2016 guideline (Sepsis-3) incorporated the data from the Protocolized Care for Early Septic Shock (ProCESS), Australasian Resuscitation in Sepsis Evaluation (ARISE), and Protocolized Management in Sepsis (ProMISe) trials which failed to confirm the survival advantage of protocolized EGDT.[42–44] In addition, Sepsis-3 not only changed the definition of classifying categories of sepsis but also emphasized the use of dynamic resuscitation markers.

It is important to discuss EGDT since the 2001 trial put the emphasis in early recognition of sepsis and a protocolized, quantitative approach to patient care for this disease state.[41] This was a single center, prospective, randomized study that included 263 patients who met the SIRS criteria and systolic BP ≤ 90 mm Hg or lactate ≥36 mg/dL (4 mmol/L). Specific resuscitation targets (ie, central venous pressure [CVP] of 8 to 12 mm Hg, MAP≥ 65, hematocrit of ≥30% [0.30], and central venous oxygen saturation [$Scvo_2$]≥ 70% [0.70]) were evaluated for reducing mortality. When EGDT and standard therapy were compared, the standard therapy led to significantly higher 28-day mortality rate. Subsequently, EGDT was quickly adopted and redefined the early, aggressive resuscitation of patients with sepsis and septic shock for the next decade. Notably, the ProCESS (1,341 subjects), ProMISe (1,234 subjects), and ARISE (1,588 subjects) investigators failed to confirm the survival benefits of protocolized targets for CVP and hemoglobin between EGDT and usual care.[42–44] However, these investigators were able to recognize the disease early allowing for quicker admission of patients from the emergency department to the inpatient care setting which may assist in overall mortality benefit in both standard therapy and EGDT.[45]

Desirable Outcomes

In addition to timely recognition and diagnosis of sepsis, other primary goals include prompt hemodynamic support, rapid identification of the pathogen, source control either medically and/or surgically, early initiation of appropriate IV antimicrobial therapy, and avoidance of complications such as organ failure and septic shock. Supportive care such as stress ulcer prophylaxis and venous thromboembolism prophylaxis is important to prevent complications during the stay in the ICU. Table 142-3 describes the selected treatment recommendations from the surviving sepsis campaign.

TABLE 142-3

Evidence-Based Treatment Recommendations and Best Practice Statements

Recommendations	Recommendation Grades

Fluid therapy	
Initial resuscitation from sepsis-associated hypotension with at least 30 mL/kg of IV crystalloid fluid within 1 hour	Strong recommendation, low evidence
Balanced crystalloids instead of normal saline for additional fluids guided by frequent assessment of dynamic measures	Weak recommendation, low evidence
Antimicrobial therapy	
IV broad-spectrum antibiotic within 1 hour of diagnosis of sepsis and septic shock against likely bacterial/fungal pathogens	Strong recommendation, moderate evidence
Empiric MRSA coverage for patients at high risk for MRSA	Best practices statement
Reassess antibiotic therapy daily with microbiology and clinical data to narrow coverage (de-escalation)	Best practices statement
Combination therapy for patients at high risk for multidrug-resistant bacterial pathogens	Weak recommendation, low quality evidence
Optimize dosing strategies based on pharmacokinetics/pharmacodynamics parameters	Best practices statement (PS)
Empiric antifungal therapy for patients at high risk of fungal infection	Weak recommendation, low evidence
Shorter duration of treatment duration using clinical evaluation and procalcitonin	Weak recommendation, low evidence
Vasopressors	
Initiate vasopressor therapy to maintain MAP ≥65 mm Hg	Strong recommendation, moderate evidence
Norepinephrine as the first-choice vasopressor	Strong recommendation, moderate evidence
Add vasopressin to norepinephrine instead of increasing norepinephrine dose to achieve adequate MAP	Weak recommendation, moderate evidence
Corticosteroids	
IV hydrocortisone for septic shock with ongoing requirement for vasopressor	Weak recommendation, low evidence
Hydrocortisone should be tapered when vasopressors are no longer required	Weak recommendation, low evidence
Glucose control	
Use insulin dosing protocol when two consecutive blood glucose levels are >180 mg/dL (10 mmol/L), targeting an upper blood glucose <180 mg/dL (10 mmol/L)	Strong recommendation, high-level evidence

Venous thomboembolism prophylaxis	
Use daily low-molecular-weight heparin (LMWH) over unfractionated heparin	Strong recommendation, moderate evidence
Stress ulcer prophylaxis	
Stress ulcer prophylaxis should be given to patients who have bleeding risk factors	Strong recommendation, low evidence
Either proton pump inhibitors or H2 receptor blockers	Weak recommendation, low evidence

MAP, mean arterial pressure. MRSA, MEthicillin-resistant *Staphylococcus aureus*.

Initial Resuscitation

④ Once the patient is recognized for sepsis and septic shock, early effective fluid resuscitation is crucial for preventing further sepsis-induced tissue hypoperfusion. The guidelines recommend at least 30 mL/kg of IV crystalloid fluid within the first 3 hours. The patient should be reassessed for hemodynamic status by measurements with better diagnostic accuracy at predicting those who are likely to respond to additional fluid.[39,46] It also recommends target MAP of 65 mg Hg to assess the need for vasopressors. While MAP indicates degree of tissue perfusion, elevated serum lactate represents tissue hypoxia and therefore should be normalized.

Fluid Therapy

Initial resuscitation effort with fluid therapy for a septic patient with tissue hypoperfusion or in septic shock is a key therapy.[47] The fluid therapy is closely related to the inflammatory cytokines that are released by the body in response to an infection. The pro-inflammatory cytokines lead to capillary leak. As the fluid travels more freely from intravascular to extravascular space, there is an overall increase in fluid in the extravascular space leading to intravascular hypovolemia. In turn, this causes end-organ edema, dysfunction, and ultimately organ failure. Therefore, understanding how the administered fluid will move within the body is essential. It is important to consider both the indication and the contraindications of available IV fluids carefully, and fluid therapy should be considered as a drug with potential benefits and risks that require frequent assessment.

There are few considerations regarding fluid therapy: initial amount, type of fluid, and duration of therapy.[48] The guidelines recommend the administration of at least 30 mL/kg crystalloids within the first 3 hours. This 30 mL/kg dose was based on observational study. Despite the lack of a robust quality of evidence this dose has been widely used in many landmark trials such as the ProCESS, ARISE, and ProMISe.[42–44] However, this amount of fluid is to be given judiciously within 3 hours. For example, if an 80-kg patient requires 30 mL/kg fluid resuscitation, the complete 2.4 L should not be administered as a single bolus dose, but as needed based on the proper assessment of fluid status and fluid responsiveness. To reduce fluid overload associated with static measurements using an invasive placement of a central venous catheter, dynamic assessment of fluid responsiveness has been used with goal-directed therapy.[49] Dynamic assessment was defined as an increase in stroke volume of more than 10% to 15% after a fluid challenge of 250 to 500 mL of crystalloids or from endogenous source by using the passive leg raise. Passive leg raise is performed by laying the patient in a supine position and raising both legs 45° at the same time. This will allow the blood from the leg to act as a bolus back to the heart. Using the passive leg raise test to check for fluid responsiveness intermittently leads to decreased use of IV fluids, especially for patients who are no longer responding adequately to IV fluid alone. Fluid therapy guided by dynamic assessment of fluid responsiveness by examining cardiac output was associated with decreased mortality compared to standard care.[49] Furthermore, the use of a dynamic assessment also decreased the length of stay in the ICU and the duration of mechanical ventilation.[50]

Guidelines recommend using ideal body weight in fluid resuscition.[39,46] However, the optimal dosing strategy for obese patients with septic shock is unknown. Dosing based on adjusted body weight was associated with improved mortality compared to actual body weight and ideal body weight.[51] Further prospective studies are needed to confirm the optimal fluid dosing in obese patients.

The type of fluid administered (ie, crystalloids such as dextrose, sodium chloride, lactated ringer, and Plasma-Lyte) or colloid (ie, albumin) serves as an important factor in resuscitation (Table 142-4). Ideally, the fluid should expand the intravascular volume without providing excess free water leading to tissue edema.[52] The Saline versus Albumin Fluid Evaluation (SAFE) trial found similar safety but no significant benefit in length of stay in ICUs and mortality between crystalloids and albumin.[53] Based on cost and accessibility, the guidelines recommend a crystalloid product (balanced solution such as lactated ringers and Plasma-Lyte or normal saline) as first-line fluid for resuscitation. Colloid (ie, albumin) can be utilized in patients who have already received considerable amount of crystalloids and continue to require fluid.[46] Hetastarch products should be avoided at all times as they increase the risk of renal failure, requiring renal replacement therapy and death in multiple studies.[46]

TABLE 142-4

Comparison of IV Fluids–Crystalloids and Colloid

	Crystalloids					Colloid
	Human Plasma	**Dextrose 5%**	**Sodium chloride 0.9%**	**Lactated ringers**	**Plasma-Lyte 148**	**Albumin 5%**
pH	7.35-7.45	4	5	6.5	5.5	7.4
Osmolarity (mOsmol/L)	291	252	308	273	294	330
Sodium (mEq/L or mmol/L)	135-145	–	154	130	140	–
Chloride (mEq/L or mmol/L)	96-106	–	154	109	98	–
Potassium (mEq/L or mmol/L)	3.5-5	–	–	4	5	–
Bicarbonate (mEq/L or mmol/L)	23-27	–	–	28 (lactate)	27 (acetate)	–
Calcium (mg/dL [mmol/L])	8.5-10.5 [2.13-2.63]	–	–	2.7	–	–
Magnesium (mEq/L [mmol/L])	1.8-2.4 [0.9-1.2]	–	–	–	3	–
Glucose (mg/dL [mmol/L])	70-100 [3.9-5.6]	50	–	–	–	–
Tonicity[a]		Isotonic[b]	Isotonic	Isotonic	Isotonic	Isotonic

[a] Tonicity is based on comparison of osmolarity of the product and human plasma. Hypotonic is defined as osmolarity < 250 mOsmol/L, isotonic is between 250 and 375 mOsmol/L, and hypertonic is > 375 mOsmol/L.

[b] Dextrose 5% acts as hypotonic solution in body. It can also increase CO_2 and lactate production.

Data from Reference 52.

Among crystalloid solutions, there is increasing evidence of potential harm in developing hyperchloridemic metabolic acidosis from excessive administration of normal saline and subsequent increased renal failure and mortality in comparison to balanced salt solutions.[54–56] The 2021 Surviving Sepsis Campaign guideline updated their nonspecific fluid recommendation to favoring balanced crystalloid over normal saline for resuscitation.[39,54,55,57]

Lastly, the total duration of fluid therapy is based on the four phases of septic shock: ROSE—resuscitation, optimization, stabilization, and evacuation.[48] *Resuscitation* phase occurs within minutes and the patient will most likely have a positive fluid balance especially after the 30 mL/kg bolus. During the second phase of optimization (within hours), the goal is to keep a neutral fluid balance between intake and output. During this time, the clinician should consider the source of infection as well as any potential organ dysfunction when deciding volume and end point in fluid administration. For instance, a patient with peritonitis-related septic shock will most likely require more fluid than pneumonia-associated septic shock. Also, it is important to avoid fluid overload to decrease the risk of ARDS and other consequences such as intra-abdominal hypertension. During the third phase, *stabilization,* which usually occurs in days, the focus should be on organ support and keeping fluid balance neutral to net negative. During this time, the patient would most likely need maintenance doses (30 mL/kg/day) of fluid only. Finally, the *evacuation* phase occurs in days to weeks, and it is suggested to keep fluid balance negative. While attempting to achieve negative balance, careful deliberation to avoid excess fluid removal is crucial. Another hypotensive event in a recovering septic shock patient can lead to a further damage.

Infection Source Control

Once the anatomic site of infection is identified, prompt efforts to eradicate that source should be made as source control has been associated with increased survival. In sepsis and septic shock, the infectious foci should be controlled once the patient is stabilized after initial resuscitation, but optimally no more than 6 to 12 hours after diagnosis. With an infected intravascular catheter, the catheter should be removed and cultured. However, infected central venous catheters without septic shock or fungemia may be treated with prolonged antimicrobial therapy if catheter removal is not practical. Urinary tract catheters should be removed if association with sepsis is suspected. Suspicion of soft tissue infections such as cellulitis or wound infection or bone involvement should lead to aggressive debridement of the affected area. Evidence of an abscess or sepsis associated with any intra-abdominal pathology (ie, GI perforation, ischemic bowel, cholecystitis, infected pancreatic necrosis) should prompt surgical intervention. Reduced survival with delayed surgical source control was reported in observational studies, and as such, the Surgical Infection Society guidelines on the management of intra-abdominal infections suggest earlier source control, allowing only a short delay for rapid resuscitation in patients who are hemodynamically unstable with sepsis.[39,46,58]

Antimicrobial Therapy

⑤ Empiric IV antibiotics should be administered immediately after initial recognition of sepsis or septic shock as a strong correlation has been reported between time to antimicrobials and mortality.[39,46,47,59]

In addition to the timing of the empiric antibiotic, administration of appropriate antibiotic, especially for multidrug-resistant bacteria, has a great impact in reducing mortality.[14,15,34,60] Inappropriate initial antimicrobial therapy occurred in about 20% of patients with septic shock, and was associated with a fivefold reduction in survival in comparison to those who received appropriate therapy (52% vs 10%, respectively).[61] Early and appropriate antibiotic administration improves the mortality in patients with sepsis and septic shock.[62] Therefore, the guidelines recommend immediate administration of IV antimicrobials, ideally within 1 hour in patients with possible septic shock or a high likelihood for sepsis, but administration within 3 hours may be reasonable in patients with possible sepsis without shock.[39]

Septic shock caused by *C. albicans* demonstrated 25% survival with initial appropriate therapy but only 4.6% survival without.[61] Among the patients with candidemia, delayed appropriate antifungal treatment, especially in the presence of septic shock and failure to achieve timely source control, was independently associated with a greater risk of hospital mortality.[18,63,64] Hence, accurate and rapid identification of candidemia is critical in prompt initiation of appropriate therapy.[37,46]

Selection of Antimicrobial Agents

The selection of an optimal empiric regimen requires assessment of several factors. Key patient factors include age, concomitant underlying diseases, chronic organ dysfunction (ie, liver or renal failure), presence of immunosuppression (ie, active cancer, neutropenia, or uncontrolled HIV infection), or presence of indwelling devices (ie, central venous lines or urinary catheter). Interviewing the patient or the patient's representative for recent hospitalization, recent history or colonization with specific pathogens, and the receipt of antimicrobials within the previous 3 months is helpful in assessing risk for infection with multidrug-resistant pathogens. Infection factors include type or anatomic site of infection, the most likely pathogens, acquisition of the organism from the community or healthcare institution, and the usual antibiotic susceptibility and resistance profile of the prevalent pathogens at the institution.

Table 142-5 lists specific empiric antimicrobial regimens for the anatomic site of infection based on the most likely pathogens.[46,58,65–68] However, general suggestions can be made when treating critically ill patients with sepsis or septic shock.

TABLE 142-5

Empiric Antimicrobial Regimens in Sepsis

Infection (site or type)	Antimicrobial regimen		
	Community-acquired	**Hospital-acquired**	**Additional considerations**
Urinary tract	Ceftriaxone or ciprofloxacin/levofloxacin	Ceftriaxone/ceftazidime or ciprofloxacin/levofloxacin	
Respiratory tract	Levofloxacin[a]/moxifloxacin or ceftriaxone + clarithromycin/azithromycin	Piperacillin/tazobactam or ceftazidime or cefepime or carbapenem[b] + levofloxacin/ciprofloxacin or aminoglycoside	± vancomycin or linezolid
Intra-abdominal	Ertapenem or ciprofloxacin/levofloxacin + metronidazole or Ceftriaxone + metronidazole	Carbapenem[b] or Piperacillin/tazobactam or Ceftazidime/cefepime + metronidazole	
Skin/soft tissue	Vancomycin or linezolid or daptomycin	Vancomycin + piperacillin/tazobactam	
Catheter-related		Vancomycin	
Unknown	Piperacillin/tazobactam or carbapenem[b]	Carbapenem[b]	

[a] 750 mg once daily.

[b] Imipenem and meropenem.

For patients at risk for sepsis or septic shock with MRSA, an anti-MRSA agent should be initiated empirically.[40] Risk factors for MRSA include prior history of MRSA infection or colonization, recent IV antibiotics or hospitalization, history of recurrent skin infections, presence of invasive devices, and hemodialysis. Vancomycin remains the mainstay of therapy for MRSA-associated infections.[69] Revised therapeutic monitoring of vancomycin guideline recommends monitoring area under the curve (AUC) over 24 hours in place of monitoring trough levels based on efficacy and nephrotoxicity data in patients with serious infections due to MRSA.[70] The 2016 Infectious Diseases Society of America (IDSA) guidelines recommend either vancomycin or linezolid for hospital-acquired/ventilator-associated pneumonia.[65] Linezolid has better lung penetration into epithelial lining fluids than vancomycin. However, linezolid was not superior to vancomycin in microbiological and clinical cure rates in patients with nosocomial pneumonia due to MRSA.[69]

Daptomycin is a cyclic lipopeptide that exhibits rapid bactericidal activity against gram-positive microorganisms including MRSA and vancomycin-resistant enterococci (VRE).[71] Daptomycin resulted in a 70% success rate for critically ill septic patients with bacteremia due to MRSA, VRE, *E. faecium* or coagulase-negative staphylococci.[71] The daptomycin cohort had significantly lower clinical failure for MRSA bacteremia when matched with vancomycin cohort patients (29% vs 45%) and lower all-cause 30-day mortality (6.1% vs 15.3%).[72]

Bloodstream infections caused by extended-spectrum beta-lactamases (ESBL)-producing Enterobacterales are associated with high rates of morbidity and mortality of up to 44% in patients with sepsis or septic shock.[73] Mortality was especially high with a delay in appropriate antimicrobial therapy.[73,74] The appropriate empiric antibiotic therapy in critically ill patients with sepsis or septic shock is crucial. Carbapenems remain active and have been regarded as the treatment of choice for serious infections due to ESBL pathogens. However, increased use of carbapenems has led to the emergence of carbapenem-resistant Enterobacterales which represents a greater threat. Piperacillin/tazobactam has been evaluated in observational studies as carbapenem-sparing therapy with conflicting results.[74,75] In a meta-analysis of 25 observational studies describing 3,824 participants who received either beta-lactam/beta-lactamase inhibitor or carbapenem as empiric or definitive therapy for ESBL-producing bacterial bloodstream infections, 30-day mortality was not significantly different.[74] However, all-cause 30-day mortality was 12.3% in the piperacillin/tazobactam group and 3.7% in the meropenem group (absolute risk difference of 8.6%) in hospitalized patients who received definitive treatment for bloodstream infections due to ceftriaxone-resistant *Escherichia coli* or *Klebsiella pneumoniae.*[76] Piperacillin/tazobactam should no longer be considered an alternative to meropenem for definitive treatment of bloodstream infection due to ESBL-producing gram-negative pathogens.

Combination therapy does not appear to be more effective than monotherapy in reducing organ failure or mortality in low-risk patients including sepsis without shock.[13] However, multidrug resistance in sepsis due to gram-negative bacteremia was strongly associated with the receipt of inappropriate empiric therapy and a threefold increase in the risk of hospital mortality.[15] The guidelines suggest using two antimicrobial agents in patients at risk of multidrug-resistant pathogens.[39] Risk factors include recent history of infection due to antibiotic-resistant organism, hospital-acquired infection, and recent history of hospitalization or use of broad-spectrum antibiotics. Once the pathogen and its susceptibilities are reported, double gram-negative coverage is no longer necessary except for highly resistant organisms. The greatest benefit of combination therapy appeared to be in patients with septic shock due to *Pseudomonas* or multidrug-resistant gram-negative bacteremia such as *Acinetobacter* and in neutropenic patients with sepsis or septic shock.[77–79] Combination therapy consisting of antibiotics from two different classes increases the probability of at least one active agent. For instance, if *P. aeruginosa* infection is suspected, beta-lactam antipseudomonal agents (ceftazidime or cefepime), antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin), or an aminoglycoside should be included in the regimen.[65]

Antifungal Therapy

Patients with candidemia are generally sicker based on their higher Acute Physiology and Chronic Health Evaluation (APACHE) II scores and have a higher mortality rate than those with bacteremia.[12] However, the use of empiric antifungal in all critically ill patients is not supported.[80] As such, clinicians should consider empiric antifungal therapy based on the risk factors for invasive *Candida* infections and no other known cause of fever.[39] The risk factors include febrile neutropenic patients after 4-7 days of broad-spectrum antibiotics, immunocompromised status, dialysis, prolonged invasive vascular devices, total parental nutrition, necrotizing pancreatitis, major surgery especially abdominal, corticosteroids, prolonged ICU stay, or fungal colonization.[39,81]

Invasive candidiasis remains the most common form of fungal infections, and empiric parenteral treatment includes echinocandins, triazoles, or a formulation of amphotericin B.[81,82] The selection depends on the clinical status of the patient, the local susceptibility of the most prevalent *Candida* species, recent exposure to antifungal agents, relative drug toxicity, and the presence of organ dysfunction or shock that would affect drug clearance. Recent exposure to antibiotics and fluconazole has been associated with fluconazole-resistant *Candida* species.[83] Fluconazole resistance among *Candida* species from bloodstream infections ranges between 12% and 28%.[16,17] *C. glabrata* was the only species that may exhibit resistance to both triazoles and echinocandins. Among the 180 isolates of *C. glabrata* isolated from nosocomial bloodstream infections, 62% were nonsusceptible to caspofungin.[16]

Triazoles (fluconazole, voriconazole) are recommended in hemodynamically stable patients who have not had previous triazole exposure and not known to be colonized with azole-resistant *Candida* species.[81] However, preferred empiric therapy for suspected invasive candidiasis in nonneutropenic patients in the ICU is an echinocandin (anidulafungin, micafungin, or caspofungin). Ecinocandins exhibit potent activity against all *Candida* species, including *C. krusei* that is typically resistant to an azole, as well as *Aspergillus* species. Empiric use of an echinocandin should be considered in most patients, despite the severity of illness including septic shock, who have been treated with other antifungal agents or suspected *C.*

glabrata or *C. krusei* infection.[81]

Resistance to fluconazole, caspofungin, and amphotericin B was reported in 28%, 2.9%, and 3.1%, respectively, of adults admitted to ICUs with invasive candidiasis who received antifungal therapy empirically.[17] Approximately 20% of the antifungal agents were changed primarily based on *Candida* susceptibility, followed by inadequate clinical response. Hospital mortality was comparable between echinocandin (caspofungin/anidulafungin) and fluconazole (56% vs 58%, respectively). Micafungin 100 mg daily was noninferior to liposomal amphotericin B 3 mg/kg daily or caspofungin 70 mg followed by 50 mg daily for the treatment of invasive candidiasis in patients with or without neutropenia. Overall treatment success was numerically lower in patients with neutropenia than those without (64% vs. 73%).[84] All three echinocandins appear to be comparable in terms of efficacy, pharmacology, and adverse effects, and the guidelines do not make a distinction or recommend a preferred agent.[81]

There was no difference in treatment efficacy or mortality outcomes in critically ill patients with invasive candidiasis receiving an amphotericin B formulation compared with those receiving an echinocandin or voriconazole.[82] However, amphotericin B was poorly tolerated. Liposomal formulation of amphotericin B (3-5 mg/kg daily) remains as an alternative to echinocandins in patients with echinocandin intolerance or toxicity.

Pharmacokinetics and Pharmacodynamic Principles of Antimicrobial Agents in Sepsis

Physiologic changes during sepsis including unstable hemodynamics, increased cardiac output, variable kidney, and hepatic perfusions, or hypoalbuminemia can dramatically alter antimicrobial pharmacokinetics.[85] Initially, high creatinine clearance can be seen in patients with normal serum creatinine because of increased renal preload. Reduced serum albumin leads to altered drug binding. Volume of distribution may be increased because of fluid accumulation from leaky capillaries into the extracellular space from aggressive fluid resuscitation. Consequently, some antimicrobial agents especially hydrophilic antimicrobials including aminoglycosides, beta-lactams, carbapenems, and vancomycin can result in suboptimal serum concentrations with standard doses. Hence, optimal dosing strategies based on pharmacokinetic and pharmacodynamic principles targets are recommended in critically ill patients.[39]

Inadequate vancomycin trough plasma concentrations in relation to the MIC of the pathogen has been associated with clinical failure in septic shock due to MRSA.[86] Trough concentrations of 15 to 20 mg/L (10.4-13.8 μmol/L) and AUC/MIC higher than 400 were associated with improved survival. The revised vancomycin dosing guideline recommends a target AUC/MIC of 400 to 600 in serious MRSA infections.[70]

Daptomycin plasma concentrations after a dose of 6 to 8 mg/kg/day for primarily staphylococcal-related infections were lower in critically ill patients than healthy volunteers.[87] Daptomycin clearance did not change significantly in patients with or without sepsis. However, volume of distribution appeared to be larger. Consequently, weight-based daptomycin dose of at least 10 mg/kg/day was recommended.[87]

The time the plasma drug concentration remains above the pathogen MIC in relation to the dosing interval (T > MIC) best describes the pharmacodynamics of beta-lactams. A minimum T > MIC of 60% of the dosing interval generally provides a good clinical response. However, sepsis or septic shock may require longer duration of T > MIC.[88] Extended infusion or continuous infusion rather than the standard 30 minutes to achieve longer T > MIC as well as a loading dosing prior to the prolonged infusion to achieve effective beta-lactam concentration without delay optimizes the pharmacokinetics and pharmacodynamics of beta-lactam antibiotics. A prolonged infusion of beta-lactams after an initial bolus dose is preferred in place of a short intermittent infusion.[39,89,90] Continuous infusion of meropenem was associated with improved clinical cure rate in patients with sepsis, greater microbiological eradication, and decreased hospital mortality compared with a standard 30-minute intermittent infusion.[91]

Based on its concentration-depending killing activity, the Sepsis-3 guidelines recommend once daily dosing of 5-7 mg/kg daily gentamicin or an equivalent aminoglycoside in patients without severely reduced renal function. This high dosing strategy yielded comparable clinical efficacy but decreased renal toxicity compared to the multiple daily dosing regimens.[46] However, suboptimal aminoglycoside concentrations may occur in the early phase of therapy in critically ill patients, suggesting higher dosing of 8 mg/kg gentamicin may be required for optimal effect.[92] Target trough concentrations of below 2 mg/L (4.18 μmol/L) should be monitored to detect potential renal toxicity.

As sepsis progresses, organ perfusion decreases because of significant myocardial depression and leads to multiple organ dysfunction. Consequently, clearance of antimicrobial agents is decreased, prolonging the elimination half-life and accumulation of metabolites. Dosing strategies need to be assessed and modified continuously through the course of treatment for optimal efficacy.

De-escalation

Empiric antimicrobial agents should be initiated immediately after the diagnosis of sepsis and septic shock is suspected due to the serious nature of the disease, but the antimicrobial regimen should be reassessed daily based on the microbiological and clinical data. This creates a potential de-escalation opportunity as part of good antibiotic stewardship to narrow down the spectrum once the pathogen has been identified to avoid unnecessary use of antimicrobials.[39,46,93] De-escalation may also prevent drug toxicities and the development of nosocomial super infections with *Candida* species, *Clostridioides*, or VRE. Improved patient care outcomes have been demonstrated with such de-escalation of antibiotic therapy. The hospital mortality rate among patients admitted to the ICU with severe sepsis or septic shock was 27% in whom therapy was de-escalated, 33% in the category of no change, and 43% in the escalation group.[94]

The data on timing or precise criteria to de-escalate in case of negative cultures is lacking. However, antimicrobial regimens should still be assessed daily for opportunity for de-escalation in response to clinical improvement including shock resolution or decrease in vasopressor requirement and/or evidence of infection resolution by biomarkers, especially PCT.[39,46]

EVALUATION OF THERAPEUTIC OUTCOMES

PCT is a serum biomarker that increases in response to endotoxins and inflammatory cytokines that are released during systemic bacterial infections, and it rises early in severe sepsis by pneumonia and bloodstream infections. Measurements of PCT concentrations may assist in determining the duration of antimicrobial therapy in sepsis.[39,46] The use of PCT concentration in critically ill patients was associated with reduced daily doses of antimicrobials, duration of antimicrobial treatment, and mortality.[95]

Duration of Therapy

The average duration of antimicrobial therapy in a patient with sepsis is 7 to 10 days in the absence of source control issues, and fungal infections can require 10 to 14 days.[46,81] However, the duration can be longer in patients with a compromised immune status, slow clinical response, large infection site, undrainable focus of infection, bacteremia with *S. aureus*, multidrug-resistant gram-negative pathogens.

However, over the past two decades, clinical trials have demonstrated that shorter courses are as efficacious as longer courses, especially with successful source control and are associated with fewer adverse events.[96,97] A 7-day course of therapy for both hospital-acquired and ventilator-associated pneumonia is recommended.[65] A short course of antimicrobial treatment (median duration of 4 days) for patients with complicated intra-abdominal infection and adequate source control had similar surgical site infection, recurrent intra-abdominal infection, or death as the control group with a median of 8 days of antibiotics whose antibiotic duration was based on symptoms (ie, fever, leukocytosis, and ileus).[97] The Surgical Infection Society recommends no more than four full days of antimicrobial therapy for patients with adequate source control and no more than 5 to 7 days in patients in whom a definitive source control was not performed.[58]

Once adequate source control is achieved, the guidelines suggest shorter duration of antimicrobial therapy in place of historically longer duration.[39] However, when optimal duration of therapy is unclear especially in the absence of identifiable causative pathogen, PCT along with clinical evaluation is suggested in determining the antimicrobial treatment duration.

Hemodynamic Support with Vasopressors

The Surviving Sepsis Campaign guidelines recommend a target MAP of at least 65 mm Hg (MAP = [SBP + 2*DBP]/3).[39,46] Achievement of a high (MAP of 80-85 mm Hg) or low (MAP of 65-70 mm Hg) target did not result in significant difference in mortality at 28 and 90 days.[98] Among the patients with pre-existing hypertension, those in the high target group had less renal dysfunction and need for renal replacement therapy. However, the incidence of newly diagnosed atrial fibrillation was significantly higher in the high target group. The number needed to treat was 9.5 to prevent one patient from necessitating renal replacement therapy.[99]

Vasopressors should be used to achieve and maintain MAP goal in fluid-resuscitation refractory shock, and they are titrated up carefully to an end point of adequate organ perfusion. There are several adrenergic receptors that are the key to understanding the mechanism of action of various vasopressors (Table 142-6). Alpha-adrenergic receptors are located in the vascular wall and in the heart, and the alpha-receptor agonists induce peripheral vasoconstriction as well as increase the duration of contraction in the heart. Beta-adrenergic receptors are primarily found in the heart. Stimulation of the beta receptors causes inotropic and chronotropic effect. Dopamine receptors are in the renal, splanchnic, coronary, and cerebral vascular beds. Dopamine receptor agonists cause vasodilation of the renal and splanchnic vessels. As dopamine is a precursor to epinephrine and norepinephrine, it affects both alpha-1 and beta-1 receptors, causing peripheral vasoconstriction and inotropy. There are three types of vasopressin receptors: V1, V2, and V3 receptors. Vasopressin works on the V1 and V2 receptors, which are in vascular smooth muscles and basolateral membrane of the collecting duck, respectively. Vasopressin contracts vascular smooth muscle mainly through the V1 receptor and retains water via V2 receptors.

TABLE 142-6

Mechanism of Action and Hemodynamic Effects of Vasopressors in Septic Shock

Drug	Receptor affinity				Physiologic outcome			
	Dopamine	Alpha-1	Beta-1	Beta-2	HR	SV	SVR	CO
Dopamine (0.5-2)[a]	+++	–	+	–	↔ or ↑	↑	↔ or ↑	↑
Dopamine (5-10)[a]	++	+	+++	+	↑	↑	↔ or ↑	↑↑
Dopamine (10-20)[a]	++	+++	++	–	↑	↑	↑↑	↑
Epinephrine	–	++++	++++	+++	↑	↑	↑↑	↑↑
Norepinephrine	–	++++	++	+	↔ or ↑	↔	↑↑	↑
Phenylephrine	–	+++	–	–	↔ or ↓	–	↑↑	↔
Vasopressin	V1 receptor				↔ or ↓	–	↑↑	↔ or ↓
Angiotensin II	AT receptor				↑	–	↑	↑

CO, cardiac output; HR, heart rate; SV, stroke volume; SVR, systemic vascular resistance; V1, vasopressin receptor 1; V2, vasopressin receptor 2.

[a] mcg/kg/min.

Data from Reference 100.

⑥ The guidelines recommend norepinephrine as the first-line agent for patients with septic shock.[40] Norepinephrine, a potent alpha-adrenergic agent with less pronounced beta-adrenergic activity than epinephrine, is the preferred vasopressor to correct hypotension in fluid refractory septic shock.[39,46,100] It increases MAP and SVR via vasoconstrictive effects on peripheral vascular beds with little changes in heart rate and less increase in stroke volume compared to dopamine. Norepinephrine is more potent than dopamine in refractory septic shock. Norepinephrine was associated with lower risk of mortality and lower risk of arrhythmia compared to dopamine.[101]

Dopamine may be considered as an alternative agent to norepinephrine in a small subset of patients who have bradycardia or are at low risk of developing arrhythmia.[46,99] Dopamine increases MAP and cardiac output by increasing the heart rate and cardiac contractility, making it potentially useful for patients with compromised systolic function. However, it is arrhythmogenic and can cause tachycardia, limiting its role in maintaining MAP.[101]

Epinephrine is a nonspecific alpha- and beta-adrenergic agonist (Table 142-6). Overall mortality at 90 days between norepinephrine and epinephrine was not significantly different in patients with septic shock.[101] However, there are several adverse effects associated with epinephrine including tachycardia, lactic acidosis, and impaired blood flow to the splanchnic system.

Optimal dosing of norepinephrine among obese patients with septic shock is important to consider as many drug studies do not include obese patients and therefore leave clinicians to extrapolate pharmacokinetic parameters from nonobese patients at bedside. Weight-based dosing of norepinephrine in obese adult patients (body mass index [BMI] > 30 kg/m^2) did not achieve goal MAP earlier than the non-WBD group, and there was no difference in mortality (23.6% vs 23.1%, respectively).[102] However, morbidly obese (BMI >40 kg/m^2) patients had significantly higher cumulative norepinephrine use in the WBD group compared to the non-WBD group, and higher cumulative dose was identified as an independent risk factor for mortality during hospitalization and at 1 year.[103] Further studies are needed to assess appropriate norepinephrine dosing strategies.

Vasopressin, also known as antidiuretic hormone, is produced in the hypothalamus and released from pituitary. In a healthy individual, it controls osmolality by stimulating the V2 receptors in the kidneys, but has little effect on BP. However, in a state of distributive shock, vasopressin binds to V1 receptors in vascular smooth muscle, which leads to vasoconstriction, thereby increasing BP. In contrast, after the initial rise in vasopressin concentration in septic shock, vasopressin level decreases to normal range due to the combination of depletion of vasopressin stores and inhibition of synthesis and release.[99] A synthetic formulation of vasopressin is dosed at 0.03 U/min without titration unlike most vasopressors, as higher doses of vasopressin have been associated with cardiac, digital, and splanchnic ischemia.

The role of vasopressin as a single vasoactive agent or in combination with norepinephrine remains controversial. The VANISH trial compared vasopressin to norepinephrine in patients with septic shock and reported no significant difference between the two groups in 28-day mortality or kidney injury.[104] The VASST trial comparing norepinephrine alone and norepinephrine with low dose (0.01-0.03 U/min) vasopressin in patients with septic shock showed similar mortality rates (39% vs. 35%, respectively). When the investigators reevaluated the VASST trial, using the new definition of septic shock from the Sepsis-3 guidelines, the sample size decreased by half, and the 28-day mortality rates were increased by about 10% for both groups.[105] Patients with less severe sepsis who received norepinephrine less than 15 mcg/min had improved survival in the combination group than in the norepinephrine alone group (36% vs 27%, respectively). Combination therapy of vasopressin with norepinephrine reduced mortality in comparison to norepinephrine alone (RR 0.91; 95% CI 0.83-0.99).[105] There was no difference in risks for digital ischemia or arrythmias. Adding vasopressin to norepinephrine is recommended (dose ranging from 0.25-0.5 mcg/kg/min) rather than increasing the norepinephrine dose to achieve adequate MAP.

The first synthetic angiotensin II was approved for the use in vasopressor refractory septic shock. In the setting of decreased renal perfusion, the angiotensinogen from liver and renin produced by the kidney come together to form angiotensin I which is then transformed to angiotensin II by angiotensin-converting enzyme. Angiotensin II ultimately increases BP by increasing sympathetic activity that stimulates pituitary gland to increase antidiuretic hormone secretion to promote sodium, chloride, and water reabsorption in the kidneys. It also continues to promote aldosterone secretion from the adrenal gland, where aldosterone will carry on the sodium and water reabsorption in the distal tubule and collecting duct of the kidney via sodium-potassium pump. Angiotensin II was evaluated in adult patients with persistent hypotension despite adequate fluid resuscitation and received > 0.2 ng/kg/min norepinephrine equivalent vasopressor use (ATHOS-3 trial).[106] A greater response in MAP was reported in 321 patients who received angiotensin II versus placebo (69.9% vs 23.4%). Patients in the ATHOS-3 trial who had AKI requiring renal replacement therapy (RRT) at initiation of angiotensin II had significantly higher 28-day survival (53% vs 30%) and discontinuation of RRT in the angiotension II group (38% vs 15%) compared with placebo.[107] Based on limited clinical experience in sepsis and safety data, synthetic angiotensin II's place of therapy in septic shock remains unclear.

Sepsis-induced myocardial dysfunction can exacerbate hemodynamic instability which may lead to worse outcomes in septic shock. Inotropic agents such as dobutamine and epinephrine have been used in patients with persistent hypoperfusion despite adequate fluid resuscitation. However, no randomized comparative trials have been conducted in this population. There was no clear reduction in mortality in dobutamine combined with norepinephrine to norepinephrine alone or between dobutamine and epinephrine.[108] Hence, the guidelines provided a weak recommendation to use either drug only in selected situations of persistent hypoperfusion despite adequate fluid resuscitation and arterial BP.[39,46]

Performance Improvement Bundle

The Surviving Sepsis Campaign recommends implementation of hospital-based performance improvement efforts such as a core set of recommendation ("bundle") because they have been associated with improved patient outcomes.[2,46] While the details of each institution's performance improvement bundle may be different, there is a common theme of improved management of patients with sepsis and septic shock.[109] Hospital mortality rates dropped 0.7% per site for every 3 months of participation. Hospital and ICU lengths of stay decreased by 4% for every 10% increase in site compliance in a 7.5-year study.[110]

⑦ The Sepsis-3 guidelines described a 1-hour care, consisting of three major components of initial treatment immediately after early recognition of sepsis: administration of fluid, administration of parenteral antibiotics, and use of vasopressor agents (Table 142-7).[47] Resolution of serum lactate is desired to indicate adequate tissue perfusion and therefore should be repeated within 2 to 4 hours of the initial level. The interpretation of repeat lactate requires careful consideration especially in patients with concomitant hepatic and/or renal failure as metabolism and elimination of lactate may be decreased in this setting. The guidelines endorse using a performance improvement program including sepsis screening and prompt initial treatment considered as standard of care for sepsis and septic shock.[39]

TABLE 142-7

Sepsis-3 (2016) Performance Improvement Checklist for Bundle-Care Compliance

One-hour bundle • Measure initial lactate • Repeat in 2 hours if initial lactate > 18 mg/dL (2 mmol/L) • Obtain cultures (blood, urine, sputum, etc.) prior to administration of antibiotics • Administer broad-spectrum IV antibiotics within 1 hour • Initial fluid resuscitation of 30 mL/kg crystalloid for hypotension or lactate ≥ 36 mg/dL (4 mmol/L) • Vasopressors if MAP < 65 mm Hg during or after completion of fluid resuscitation
Outcome measurements: • Length of stay in ICU and hospital • Rate of organ dysfunction • Mortality rate

MAP, mean arterial pressure.

Data from References 46,47.

Adjunctive Therapies

Sepsis and septic shock present multitudes of complications in a relative short span of time. In addition to prompt initiation of a performance improvement bundle, several adjunctive therapies including transfusions of blood products, oxygen supplement, mechanical ventilation, or RRT may be required. Key pharmacological adjunctive therapies are described below.

⑧ In Sepsis-3 guidelines, IV hydrocortisone is recommended for adult patients with septic shock who are hemodynamically unstable after initial resuscitation with IV fluids and vasopressors.[46] Cortisol levels vary widely in patients with septic shock, and an increased mortality has been associated with both low and high serum cortisol levels. Data on the benefits of corticosteroids as adjunct therapy in patients with sepsis and septic shock are conflicting with regards to reduction of overall mortality.[111–117] A significant shock reversal and reduction in mortality were reported in patients with septic shock unresponsive to fluid resuscitation and vasopressors for more than an hour and had relative adrenal insufficiency who received prolonged courses (>5 days) of low-dose corticosteroid therapy compared to placebo (38% vs. 44%; relative risk 0.84).[111] The Corticosteroid Therapy of Septic Shock (CORTICUS) found no survival benefit for patients who were unresponsive to adequate fluid replacement and required vasopressors, with or without adrenal insufficiency.[112] However, CORTICUS included patients with septic shock regardless of their responsiveness to vasopressor therapy. Subsequent meta-analyses and systematic reviews continue to present conflicting data. Low-dose corticosteroids reduced 28-day mortality, increased shock reversal, and reduced organ injury based in an analysis of 22 randomized controlled trials.[113] Another systematic review of 35 trials of sepsis detected no significant benefit on mortality.[114]

After publication of the Sepsis-3 guidelines, two large, randomized, blinded, multicenter, controlled trials of low-dose corticosteroids use in patients with septic shock did not confirm or refute previously published data on reduction of mortality.[115,116] However, these landmark studies offer other practical benefits of low-dose corticosteroids. Both trials clearly defined adequate fluid resuscitation, vasopressor-dependent shock, and appropriate antimicrobial therapy. The 90-day mortality in the Adjunctive Corticosteroid Treatment in Critically Ill Patients with Septic Shock (ADRENAL) trial was similar between continuous infusion of hydrocortisone 200 mg/day for maximum of 7 days and placebo (27.9% vs. 28.8%, respectively).[115,117] The 90-day mortality in the Activated Protein C and Corticosteroids for Human Septic Shock (APROCCHSS) trial was 43% with hydrocortisone 50 mg IV bolus every 6 hours plus fludrocortisone 50 mcg tablet via a nasogastric tube once daily for 7 days and 49% with placebo.[116] The dramatic difference in the mortality data may rise from the patients' severity of illness. The patients from the APROCCHSS trial may have been more seriously ill based on their SOFA and APACHE II scores and had higher proportions of patients who required RRT or who had and bacteremia. Regardless, both trials showed significantly faster resolution of shock and increase in vasopressor-free days, providing reassurance of short-term benefits of low-dose hydrocortisone in selected patients even if there is not clear benefit for short or long-term mortality.[115–118]

The 2021 guidelines updated the recommendation to adding low dose hydrocortisone 200 mg/day for patients with septic shock who require ongoing norepinephrine dose of >0.25 mcg/kg/min at least 4 hours to maintain the target MAP.[39] Continuous infusion of hydrocortisone may prevent a significant increase in blood glucose associated with repetitive bolus injections. Steroid should be tapered when vasopressors are no longer required as hemodynamic and immunologic rebound effects have been reported with abrupt cessation of corticosteroids.[46]

⑨ Hyperglycemia and insulin resistance are frequently associated with sepsis regardless of the presence of diabetes prior to sepsis, and more severe hyperglycemia is associated with higher morbidity and mortality.[2,46] The NICE-SUGAR trial, the largest study to date on glucose control in ICU patients, reported a higher incidence of mortality at 90 days with intensive insulin therapy (target glucose range of 81-108 mg/dL [4.5-6.0 mmol/L]) than with conventional therapy (target of < 180 mg/dL [10.0 mmol/L]).[119] Intensive insulin therapy targeting blood glucose of 80 to 110 mg/dL (4.4 to 6.1 mmol/L) in septic patients did not improve overall mortality and was associated with a higher incidence of hypoglycemia (blood glucose less than 40 mg/dL [2.2 mmol/L]).[120] The Sepsis-3 guidelines recommended initiating insulin when two consecutive blood glucose levels are greater than 180 mg/dL (10.0 mmol/L) based on the NICE-SUGAR trial. However, the guidelines do not give a specific target glucose range other than monitoring glucose of less than 180 mg/dL (10 mmol/L) every 1 to 2 hours until the glucose levels and insulin requirements are stable to avoid hypoglycemia.[46]

A meta-analysis of 35 randomized controlled trials compared four blood glucose targets (180 mg/dL [10 mmol/L]) and risks of hospital mortality and hypoglycemia.[121] There were no significant differences in mortality among the groups. However, lower target ranges (less than 110 [6.1 mmol/L] and 110-144 mg/dL [6.1 - 8 mmol/L]) were associated with a four- to ninefold increased risk of hypoglycemia in comparison to the higher target ranges. No significant difference in risk of hypoglycemia was noted between a range of 144-180 mg/dL (8-10 mmol/L) and greater than 180 mg/dL (10 mmol/L). The current recommendation remains to initiate insulin therapy at a glucose level of greater than 180 mg/dL (10 mmol/L) with a target range between 144 and180 mg/dL (8-10 mmol/L).[39]

Pharmacologic venous thromboembolism (VTE) prophylaxis should be initiated in all patients admitted to the ICU with sepsis and septic shock.[39,46]

Overall, the incidence of VTE in the ICU is approximately 10%. However, the incidence was much higher (37.2%) in patients with sepsis and septic shock which may increase the length of stay in ICU (18.2 vs. 13.4 days, respectively).[122]

There is limited data comparing low molecular weigth heparin to unfractionated heparin in VTE prophylaxis among septic patients. However, the overall rate of VTE and pulmonary embolism was lower in critically ill patients receiving LMWH in comparison to unfractionated heparin administered twice daily, and overall mortality was also reduced, albeit not significant.[123] The guideline continues to recommend LMWH over unfractionated heparin for VTE prophylaxis in patients with sepsis or septic shock.[39] If pharmacologic prophylaxis is contraindicated, mechanical prophylactic measures should be considered.[125]

An international prospective cohort study reported clinically important GI bleeding occurred in 2.6% in critically ill adult patients.[124] Prophylaxis with either a proton pump inhibitor (PPI) or histamine 2 receptor antagonist reduced the risk of GI bleeding in comparison to no prophylaxis.[124] The use of pantoprazole versus placebo did not demonstrate any effect on mortality.[126] However, PPI use did reduce GI bleeding. A higher risk of *C. difficile* infections was noted with PPI use.[39]

The guidelines continue to recommend stress ulcer prophylaxis should be initiated in all patients with sepsis and septic shock who have risk factors for GI bleeding.[39] Risk factors for clinically relevant GI bleeding include shock, coagulopathy, and chronic liver disease.[125] The selection of agent should also consider patient's renal, liver, hematologic dysfunction, as dose adjustments may be necessary. Although preventing clinically significant GI bleeding is important, it also must be balanced with potential adverse events from decreasing pH of the stomach such as possibility of developing *C. difficile* infection.[46]

ABBREVIATIONS

AKI	acute kidney injury
APACHE	acute physiology and chronic health evaluation
ARDS	acute respiratory distress syndrome
AUC	area under the curve
BMI	body mass index
BP	blood pressure
CVP	central venous pressure
DIC	disseminated intravascular coagulation
EGDT	early goal-directed therapy
ESBL	extended-spectrum beta-lactamases
GI	gastrointestinal
HIV	human immunodeficiency virus
H2RA	histamine 2 receptor antagonist
ICU	intensive care unit
IV	intravenous
IL	interleukin
IL-1RA	interleukin-1 receptor antagonist
LMWH	low-molecular-weight heparin
MAP	mean arterial pressure

MIC	minimum inhibitory concentration
MRSA	methicillin-resistant *Staphylococcus aureus*
PCT	procalcitonin
PPI	proton pump inhibitor
RRT	renal replacement therapy
$Scvo_2$	central venous oxygen saturation
SIRS	systemic inflammatory response syndrome
SOFA	sequential organ failure assessment
SVR	systemic vascular resistance
T>MIC	time above minimum inhibitory concentration
TNF	tumor necrosis factor
qSOFA	quick sequential organ failure assessment
VRE	vancomycin-resistant enterococci
VTE	venous thromboembolism
WBC	white blood cell
WBD	weight-based dosing

SELF-ASSESSMENT QUESTIONS

1. Regarding the common pathogens in sepsis and septic shock, which of the following statements is correct?
   - A. Since the late 1970s, gram-positive organisms continued to be the predominant pathogens.
   - B. Enterococci species are the common gram-positive pathogens.
   - C. *Escherichia coli* is the most frequent cause of sepsis fatality.
   - D. Non-albicans Candida species have become the most common causes of fungal sepsis.
2. A complication associated with sepsis is:
   - A. Persistent hypotension.
   - B. Disseminated intravascular coagulation.
   - C. Acute respiratory distress syndrome.
   - D. Acute kidney injury.
   - E. All of the above.
3. The preferred treatment option for a 56-year-old male with community-acquired pneumonia who was prescribed azithromycin for sinusitis is:
   - A. Ertapenem.
   - B. Moxifloxacin.
   - C. Tigecycline.
   - D. Doxycycline.
   - E. Clarithromycin.
4. Which of the following treatment regimen is preferred in case of nosocomial pneumonia with a suspicion for *Pseudomonas aeruginosa*?
   - A. Ampicillin/sulbactam
   - B. Ceftriaxone plus azithromycin
   - C. Colistin
   - D. Ceftazidime plus levofloxacin
   - E. Vancomycin plus ertapenem
5. Which of the following agents may not be used to treat hospital-acquired pneumonia secondary to methicillin-resistant *S. aureus*?
   - A. Daptomycin
   - B. Vancomycin
   - C. Linezolid
   - D. Telavancin
   - E. Ceftarolin
6. Initial resuscitation bundle should take place within 1 hour in patients with sepsis or sepsis-induced tissue hypotension. What are the

recommended activities?

A. Norepinephrine if not responsive to fluid resuscitation

B. Fluid resuscitation with crystalloid

C. Empiric broad-spectrum antibiotics

D. Blood cultures prior to antibiotic administration

E. All of the above.

7. The preferred agent for a 37-year-old male with an advanced stage of AIDS and candidemia is:

   A. Imipenem.

   B. Caspofunction.

   C. Itraconazole.

   D. Ketoconazole.

8. Regarding hemodynamic support, which of the following agent is the best initial therapeutic intervention?

   A. Five percent albumin

   B. Lactated ringer solution

   C. Normal saline

   D. Norepinephrine

   E. Dopamine

9. Norepinephrine affects the following receptors EXCEPT:

   A. Alpha-1.

   B. Dopamine.

   C. Beta-1.

   D. Beta-2.

10. Invasive candidiasis can be treated with the following agents EXCEPT:

    A. Fluconazole.

    B. Caspofungin.

    C. Amphotericin B deoxycholate.

    D. Itraconazole.

11. Which of the following agents is most effective against *Candida glabrata*?

    A. Fluconazole

    B. Clotrimazole

C. Caspofungin

D. Itraconazole

E. Ketoconazole

12. Which of the following factors affect the overall prognosis?

A. Advanced age

B. One or more organ failure

C. Positive blood culture of *Pseudomonas aeruginosa*

D. Elevated lactate level and slow clearance

E. All of the above

13. Which of the following conditions poses least risk of mortality?

A. Acute kidney injury

B. Obstructive urinary tract infection

C. Ischemic bowel obstruction

D. Septic shock

E. Multiple organ dysfunction

14. What is the regimen of choice for bloodstream infection caused by ESBL-producing *Klebsiella pneumoniae*?

A. Ceftriaxone

B. Colistin

C. Ertapenem

D. Piperacillin/tazobactam

E. Gentamicin

15. What is the appropriate IV fluid therapy for a 80-kg male patient with septic shock?

A. 1,000 mL normal saline bolus

B. 2,400 mL albumin bolus

C. 0.5 mcg/kg/min dopamine continuous infusion

D. 2,400 mL normal saline within 1 hour

E. 1,000 mL Hetastarch

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D**. Non-albicans Candida species collectively is more frequently isolated over C. albicans specifically in sepsis or septic shock due to fungal infection.

Gram-negative organisms continued to be most common. *Escherichia coli* is the most common gram-negative pathogen but *Pseudomonas aeruginosa* has been associated with increasing mortality. *S. aureus* is the most common gram-positive pathogen in sepsis.

2. **D**. Sepsis may rapidly lead to multiple complications of shock, disseminated intravascular coagulation, and multiple organ dysfunction such as acute kidney injury and acute respiratory distress syndrome.

3. **B**. Recent usage of azithromycin increases the risk of antibiotic-resistant *Streptococcus pneumoniae*, favoring respiratory fluoroquinolone such as moxifloxacin for treatment of community-acquired pneumonia.

4. **C**. Ampicillin/sulbactam and ceftriaxone plus azithromycin regimens lack activity against *P. aeruginosa*. In the absence of risk of methicillin-resistant *S. aureus*, addition of vancomycin is not recommended.

5. **A**. Daptomycin exhibits activity against MRSA. However, it is inactivated by pulmonary surfactant, rendering it less optimal choice for pneumonia.

6. **D**. Performance improvement bundle consisting of administration of IV fluids, parenteral antibiotics, and vasopressor with the first hour of sepsis recognition decreases mortality and lengths of stay in hospital and ICU.

7. **B**. Patients with fungemia generally have a higher mortality rate than bacteremia. In addition, increasing reports of azole-resistant Candida species and immunocompromised patient risk factor required echinocandin exhibiting potent activity against all Candida species and consistent serum concentrations.

8. **A**. Crystalloids (ie, normal saline, dextrose, lactated ringer, and Plasma-Lyte) are generally recommended over colloid (ie, Albumin) based on similar efficacy, accessibility, and lower cost. Among crystalloids, the guideline favors balanced crystalloid (Plama-Lyte) over normal saline due to less incidence of hyperchloridemic metabolic acidosis.

9. **B**. Norepindephrine has highest affinity to alpha-1 receptors, followed by beta-1 and beta-2 receptors.

10. **D**. Treatment of invasive candidiasis includes parenteral administration of echinocandins, triazoles, or a formulation of amphotericin B. However, itraconazole is only available as an oral capsule and solution.

11. **C**. Empiric use of an echinocandin should be considered in most patients, despite the severity of illness including septic shock, who have been treated with other antifungal agents or suspected *C. glabrata* or *C. krusei* infection.

12. **D**. As the number of failing organs increased from one to four or more, the mortality rate increased from 15% to 40%. Patients with candidemia generally have septic shock, and the mortality rate was approximately 50%. An elevated serum lactate of 36 mg/dL (4 mmol/L) upon initial presentation and persistent elevation were associated with an increased mortality rate. Combination of septic shock and hyperlactatemia further increased the 28-day mortality rate.

13. **B**. Higher mortality rate was reported in intra-abdominal infection due to ischemic bowel compared to obstructive uropathy-associated urinary tract infection and acute kidney injury (75%, 26%, and 22%, respectively).

14. **C**. Ceftriaxone is ineffective against ESBL-producing *K. pneumoniae*, and piperacillin/tazobactam failed to demonstrate noninferiority over carbapenem in bacteremia due to ceftriaxone-resistant *K. pneumoniae*. Colistin has limited usage due to significant toxicity.

15. **B**. Early effective fluid resuscitation is crucial for preventing further sepsis-induced tissue hypoperfusion. Initial resuscitation with 30 mL/kg of IV balanced crystalloid fluid is recommended.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 143: Superficial Fungal Infections

Thomas E.R. Brown; Linda Dresser

KEY CONCEPTS

KEY CONCEPTS

① Vulvovaginal candidiasis (VVC) is a fungal infection of the vagina that can be classified as uncomplicated or complicated. This classification is useful in determining appropriate pharmacotherapy.

② *Candida albicans* is the major pathogen responsible for VVC. The number of cases of non–*C. albicans* species appears to be increasing.

③ Signs and symptoms of VVC are not pathognomonic, and reliable diagnosis must be made with laboratory tests including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy.

④ *C. albicans* is the predominant species causing all forms of mucosal candidiasis. Important host and exogenous risk factors have been identified that predispose an individual to the development of mucosal candidiasis. In oropharyngeal and esophageal candidiasis, the key risk factor is impaired host immune system.

⑤ A topical antimycotic agent is the first choice for treating oropharyngeal candidiasis. Systemic therapy can be used in patients who are not responding to an adequate trial of topical treatment or are unable to tolerate topical agents and in those at high risk for systemic candidiasis. Fluconazole and itraconazole are the most effective azole antimycotic agents.

⑥ For esophageal candidiasis, topical agents are not of proven benefit; oral fluconazole or itraconazole solution is the first choice.

⑦ Optimal antiretroviral therapy is important for the prevention of recurrent and refractory candidiasis in patients with human immunodeficiency virus (HIV) infection.

⑧ Primary or secondary prophylaxis of fungal infection is not recommended routinely for HIV-infected patients; use of secondary prophylaxis should be individualized for each patient.

⑨ Topical antimycotic agents are first-line treatment for fungal skin infections. Oral therapy is preferred for the treatment of extensive or severe infection and those with tinea capitis or onychomycosis.

⑩ Oral antimycotic agents such as terbinafine and itraconazole are first-line treatment for toenail and fingernail onychomycosis.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the YouTube video entitled “Watch and Learn KOH preparation” by Richard Usatine, MD. This 4-minute video demonstrates the quickest and most accurate way to diagnose fungal skin infections. The video is useful in visualizing fungal elements such as hyphae and pseudohyphae.

INTRODUCTION

Superficial mycoses are among the most common infections in the world and the second most common vaginal infections in North America. Mucocutaneous candidiasis can occur in three forms—oropharyngeal, esophageal, and vulvovaginal disease—with oropharyngeal and vulvovaginal disease being the most common. Over the past 15 to 20 years, the occurrence rates of some fungal infections have increased dramatically. The prevalence of fungal skin infections varies throughout different parts of the world, from the most common causes of skin infections in the tropics to relatively rare disorders in the United States.

VULVOVAGINAL CANDIDIASIS

① *Vulvovaginal candidiasis* (VVC) refers to infections in individuals with or without symptoms who have positive vaginal cultures for *Candida* species. Depending on episodic frequency, VVC can be classified as either sporadic or recurrent.[1] This classification is essential to understanding the pathophysiology, as well as the pharmacotherapy, of VVC. Furthermore, VVC may be defined as uncomplicated, which refers to sporadic infections that are susceptible to all forms of antifungal therapy regardless of the duration of treatment, or complicated, in which consideration of factors affecting the host, microorganism, and pharmacotherapy all have an essential role in successful treatment.[1] Complicated VVC includes recurrent VVC, severe disease, non–*C. albicans* candidiasis, and host factors, including diabetes mellitus, immunosuppression, and pregnancy.[1]

Epidemiology

There is minimal information on the incidence and prevalence of VVC. Healthcare workers are not required to report cases of VVC; therefore, estimates are derived from self-reported histories. Epidemiologic data are limited because VVC usually is diagnosed without microscopy and/or cultures, and antifungal nonprescription preparations are available for self-treatment.[1] Fifty to 72% of females will have had at least one episode of VVC.[1] It is rare before menarche and increases dramatically at about 20 years of age, with the peak incidence between age 30 and 40 years. It is associated with the initial act of sexual intercourse. Between 40% and 50% of females who experience one episode of VVC experience a second episode, and 5% experience recurrent VVC.[2] The incidence after menopause remains unknown. However, healthy postmenopausal females with vulvar conditions taking hormone replacement therapy (HRT) were more prone to developing VVC than those who were not taking HRT (culture-positive, clinical VVC in 49% on HRT vs 1% on those not on HRT).[3]

Costs from VVC can be direct (medical visits and self-treatment) and indirect (nonmedical expenses, eg, time losses from work, costs of travel, and time required in obtaining treatment). There are 6 million visits to healthcare providers each year, resulting in more than $1 billion spent annually on these medical visits and self-treatment.[4] Nonprescription sales for feminine itch and yeast treatments were $302 million in the United States in 2017.[5]

Pathophysiology

② *C. albicans* is the major pathogen responsible for VVC, accounting for 80% to 92% of symptomatic episodes. The remainder are caused by non–*C. albicans* species, with *Candida glabrata* dominating.[6] The number of cases of non–*C. albicans* candidiasis appears to be increasing, possibly related to the use of nonprescription vaginal antifungal preparations and short-course therapy and/or the increased use of long-term maintenance therapy in preventing recurrent infections.[1]

Candida species can act as commensal members of the vaginal flora. Asymptomatic colonization with *Candida* species occurs in 10% to 20% of females of reproductive age.[6,7] *Candida* organisms are dimorphic; blastospores are responsible for colonization (transmission and spread), whereas germinated *Candida* forms are associated with tissue invasion and symptomatic infections.[8] To colonize the vagina, *Candida* species must be able to attach to the mucosa. The attachment process is complex. Not only are candidal surface structures important for attachment, but appropriate receptors for attachment must be present in the epithelial tissue. Not all females have the same range of receptors, which may explain variation in colonization.[7] Changes in the host's vaginal environment or response are necessary to induce a symptomatic infection. Unfortunately, in most cases of symptomatic VVC, no precipitating factor can be identified.[8]

Risk Factors

Several factors predispose a woman to VVC. VVC is not considered to be a sexually transmitted disease, although sexual factors can be important. There is a dramatic increase in the frequency of VVC when females become sexually active. In addition, oral-genital contact can increase the risk.[1] However, the treatment of asymptomatic partners is not recommended.[6] Contraceptive agents, including the diaphragm with spermicide, the contraceptive sponge, and the intrauterine device, increase the risk of VVC.[9] *Candida* species are capable of adhering to the contraceptive vaginal ring.[9] Oral contraceptive users demonstrated increased risk of candidiasis; however, these reports were with the higher-dose oral contraceptive pills, and the risk may not be as great with the lower-estrogen-dose oral contraceptives.[8]

Antibiotic use can increase the risk of VVC, but it is significant in only a small number of females. The mechanism by which antibiotics can increase the risk of VVC is unknown; colonization, however, is a prerequisite.[1] Three days of antibiotics increased the prevalence of asymptomatic vaginal colonization of *Candida* and the incidence of symptomatic VVC.[10] Diet (excess refined carbohydrates), douching, and tight-fitting clothing often are listed as important risk factors; however, no association has been established between these factors and increased risk of VVC.[1]

Clinical Presentation

③The clinical presentation of VVC is given in Table 143-1.[1,6] These signs and symptoms are not pathognomonic, and a reliable diagnosis cannot be made without laboratory tests. The value of self-diagnosis and the success of self-treatment is limited. Self-diagnosis has a sensitivity of 35%, a specificity of 89%, and a positive predictive value of 62%. Only 30% to 40% of females that complained of vaginal itiching had VVC.[8] The American College of Obstetricians and Gynecologists (ACOG) recommends that whenever possible females requesting treatment for VVC should be examined and evaluated. They only recommend self-diagnosis in compliant females with multiple confirmed prior cases of VVC who report the same symptoms. They further recommend that if these individuals fail to improve on a short course of therapy, they be evaluated for a further diagnosis.[11] Therefore, in most instances the diagnosis should be based on both clinical presentation and investigations, including vaginal pH, saline microscopy, and 10% potassium hydroxide (KOH) microscopy of vaginal discharge. The vaginal pH remains normal in VVC, and microscopic investigations should detect blastospores or pseudohyphae. *Candida* cultures usually are not required in the diagnosis of uncomplicated VVC. However, they are recommended when an individual presents with classic signs and symptoms of VVC, has a normal vaginal pH, but microscopy is inconclusive or recurrence is suspected.[6]

TABLE 143-1

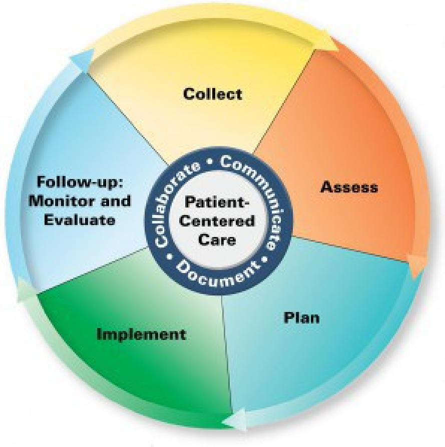
Clinical Presentation of Vulvovaginal Candidiasis

General	Often involves both the vulva and the vagina
Symptoms	Intense vulvar itching, soreness, irritation, burning on urination, and dyspareunia
Signs	Erythema, fissuring, curdy “cheese”-like discharge, satellite lesions, edema
Laboratory tests	Vaginal pH—normal, saline, and 10% KOH microscopy—blastospores or pseudohyphae
Other diagnostic tests	*Candida* cultures not recommended unless classic signs and symptoms with normal vaginal pH and microscopy are inconclusive or recurrence is suspected

KOH, potassium hydroxide.

PATIENT CARE PROCESS

Patient Care Process for Vulcovaginal Candidiasis



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (age, pregnancy status)
- Patient medical history (previous vaginal infections, diabetes mellitus)
- Social history (sexual activity)
- Current meds (oral contraceptives, antibiotics)

Assess

- Symptoms consistent with VVC (itching, clumpy white vaginal discharge)
- Absence of fever, pelvic pain, colored or foul smelling vaginal discharge
- Possibility of sexually transmitted disease

- Recurrence of symptoms from previous vaginal infection

Plan*

- Remove predisposing risk factors if possible
- Select a drug therapy regimen including specific antifungal(s) dose, route, frequency, and duration (Table 143-2)
- Education of the patient regarding causes of VVC and the selected treatment
- Refer to other healthcare providers if complicated or recurrent VVC or risk factors for sexually transmitted disease

Implement

- Provide patient counselling (avoid harsh soaps, perfumes, hot tub use, contraceptive use)
- Keep vaginal area clean and dry, avoid constrictive clothing
- Self-assessment of symptom relief is appropriate

Follow-Up: Monitor and Evaluate

- Monitor for complete resolution of symptoms within 24-48 hours of initiation of therapy (itching, clumpy white discharge)
- Determine the presence of adverse effects (nausea, abdominal discomfort, vaginal irritation)
- Refer to other healthcare providers if symptoms do not resolve despite adherence

******Collaborate with patient, caregivers, and other healthcare professionals.*

Treatment

Goals of Therapy

The goal of therapy is complete resolution of symptoms in patients who have symptomatic VVC. A test of the cure is not necessary if symptoms resolve.[6] Antimycotic agents used in the treatment of VVC do not meet the definition of being fungicidal agents because of their slower killing rate. At the end of therapy, the number of viable organisms drops below the detectable range. However, by 6 weeks after a course of therapy, 25% to 40% of females will have positive yeast cultures and remain asymptomatic.[1] Asymptomatic colonization with *Candida* species does not require therapy.

General Approaches to Treatment

The approach to therapy is to remove or improve any predisposing factors if they can be identified. An effective antimycotic agent should have limited local and systemic side effects, a high cure rate, and easy administration. Additionally, it would be advantageous to use a treatment that resolves symptoms within 24 hours, has broad antimycotic activity (to cover increasing rates on non–*C. albicans* species), prevents recurrence, and can be used over a shortened period of time, such as 1 to 3 days. Many topical azoles antifungals (such clotrimazole and miconazole) are available without a prescription, and although this may increase public access to these medications, there is concern that having them available without a prescription may lead to inappropriate use. A study conducted using 10 actors as simulated patients who visited 60 pharmacies found that vaginal antimycotics were more likely to be appropriately provided to individuals as more information was exchanged, if interactions involved a pharmacist, and if questions regarding specific symptoms were used.[12]

Patients should be advised to avoid harsh soaps and perfumes that can cause or worsen vulvar irritation. The genital area must be kept clean and dry by avoiding constrictive clothing and frequent or prolonged exposure to hot tub use.[13] Douching is not recommended for either prevention or treatment.[8] Cool baths can soothe the skin.[13] The value of oral use of lactobacillus remains unclear, and according to a systematic review the use of lactobacilli containing vaginal products does not hold much promise. There was no evidence of vaginal colonization after probiotic use.[14]

Treatment of VVC will be considered to have positive outcomes if the symptoms of VVC are resolved within 24 to 48 hours and no adverse medication events are experienced. Self-assessment of symptom relief is appropriate for most cases of VVC. If symptoms remain unresolved or recur, then further testing and treatment can be required.

Pharmacologic Treatments

Uncomplicated Vulvovaginal Candidiasis

Uncomplicated VVC is an infection in females who are not immunocompromised, do not have diabetes, and are not pregnant. There are many different products, routes, and durations of treatment. No product route or duration of treatment is superior to any other. Cure rates for uncomplicated VVC are between 80% and 95% with topical or oral azoles and between 70% and 90% with nystatin preparations. Table 143-2 lists many available topical and oral preparations for the treatment of uncomplicated VVC. There are no significant differences in in vitro activity or clinical efficacy among the topical azole agents.[1,6,11,13] Some topical products can cause vaginal burning, stinging, or irritation; conversely, the vehicle used in topical creams or gels can provide initial symptomatic relief.[1] Of note, most topical preparations can decrease the efficacy of latex condoms and diaphragms.

TABLE 143-2

Treatment for Uncomplicated Vulvovaginal Candidiasis

Active Ingredient	Preparation	Regimen
Nonprescription/Topical Vaginal Products		
Butoconazole	2% cream	One applicator × 3 days
Clotrimazole	1% cream	One applicator × 1 day
	100 mg tablet	One 100 mg tablet × 7 days
	2% cream	One applicator × 1 day
	200 mg tablet	One 200 mg tablet × 3 days
	10% cream	One applicator × 1 day
	500 mg tablet	One 500 mg tablet × 1 day
Miconazole[a]	2% cream	One applicator × 1 day
	100 mg suppository	One 100 mg suppository × 7 days
	200 mg suppository	One 200 mg suppository × 3 days
	1,200 mg ovule	One ovule × 1 day
Ticonazole	2% cream	One applicator × 3 days
	6.5% cream	One applicator × 1 day
Prescription/Topical		
Nystatin	100,000 unit tablet	One tablet × 14 days
Terconazole	0.4% cream	One applicator × 7 days
	0.8% cream	One applicator × 3 days
Oral Products		
Fluconazole	150 mg	One tablet × 1 day

[a] The FDA warns of the possible increase in the anticoagulant effects of warfarin with concomitant use.

Oral azoles (such as fluconazole or itraconazole) have been used in the treatment of VVC and are therapeutically equivalent to topical therapies.[1] Patients may prefer oral therapy because of its convenience.[15] There were no differences between the routes in short-term mycologic cure rates. There was a significant difference between long-term cure rates in favor of long-term follow-up; however, the clinical significance of this finding is uncertain.[16]

In the treatment of uncomplicated VVC, the duration of therapy is not critical. Cure rates with different lengths of treatment have not demonstrated that one duration of therapy is significantly better.[15–17] Shorter-duration therapies (eg, clotrimazole 1-day therapy) consist of higher concentrations of azoles that maintain the local therapeutic effect for up to 72 hours and allow for resolution of signs and symptoms.[18] There was less than 7% difference in short-term cure rates or improvement between any two treatments in any two studies and no significant differences in short- or long-term clinical cure rates among 1-day regimens.[17] There are many options for the treatment of uncomplicated VVC, and selection of an azole antimycotic agent should be based primarily on an individual patient's preference and past experience.[17]

Complicated Vulvovaginal Candidiasis

Complicated VVC occurs in patients who are immunocompromised or have uncontrolled diabetes mellitus or are pregnant.[1] Unlike with uncomplicated VVC, product selection is important in these individuals. The duration of therapy and/or route of administration is important. Immunocompromised females or those with uncontrolled diabetes mellitus need a more aggressive treatment plan and treatment should be lengthened to 10 to 14 days regardless of the route of administration.[11] Therapeutic options include those listed in Table 143-2; however, regimens should be continued for 10 to 14 days. Cure rates increased from 67% with single-dose oral fluconazole therapy in females with complicated VVC therapy to 80% when the 150 mg dose of fluconazole was repeated 72 hours after the initial dose.[19]

VVC during pregnancy can be considered complicated because consideration of host factors such as hormonal changes that can affect normal flora are essential in selecting therapeutic regimens. Topical agents are considered to be safe throughout pregnancy. Imidazole topical agents (such as fluconazole) were more effective than nystatin for VVC during pregnancy and treatment for 7 days was more effective than treatments of 4 days or less.[20] Oral therapy is not recommended as larger doses of fluconazole have been linked to birth defects.[8] Instead, the ACOG recommends a topical imidazole therapy for 7 days.[11]

Recurrent Vulvovaginal Candidiasis

Recurrent vulvovaginal candidiasis (RVVC) is defined as having more than four episodes of VVC within a 12-month period. Fewer than 5% of females develop RVVC, and its pathogenesis is poorly understood. A proper diagnosis should be obtained to rule out other infections or nonmycotic contact dermatitis. RVVC is best treated in two stages: an initial intensive stage followed by prolonged antifungal therapy to achieve mycologic remission (with 150 mg oral fluconazole daily for 10 days followed by 6 months of fluconazole 150 mg weekly). Ninety percent of females receiving 10-day initial and 6-month prolonged treatments were symptom free for the 6 months following initial treatment, and there were 50% fewer symptomatic episodes in the 6 months (compared with placebo treatment after the initial 10 days).[21] The Infectious Diseases Society of America recommends 10 to 14 days of induction therapy with a topical or oral azole, followed by 150 mg of fluconazole once weekly for 6 months for recurring *Candida* VVC.[22,23]

Antifungal-Resistant Vulvovaginal Candidiasis

Resistance to azole antimycotics should be considered in individuals who have persistently positive yeast cultures and fail to respond to therapy despite adherence to prescribed regimens.[1] These infections can be treated with boric acid or 5-flucytosine.[24] Boric acid is administered as a 600 mg intravaginal capsule daily for 14 days of induction therapy, followed by a maintenance regimen of one capsule intravaginally twice weekly. Boric acid should not be administered orally, as it is toxic. Flucytosine cream is administered vaginally, 1,000 mg inserted nightly for 7 days. The prevalence of *C. glabrata* is higher in those with diabetes. In a study of patients with diabetes and VVC, 68% had isolates for *C. glabrata* compared with 28.8% for *C. albicans.* Those with *C. glabrata* had significantly higher mycological cure rates with 600 mg of boric acid suppositories for 14 days compared with a single dose of fluconazole 150 mg.[25]

OROPHARYNGEAL AND ESOPHAGEAL CANDIDIASIS

Oropharyngeal and esophageal candidiasis are common and localized infections that occur in patients with human immunodeficiency virus (HIV) infection, diabetes, leukemia, and other malignancies. These infections are also associated with antimicrobial therapy, steroid use, radiation therapy, and denture use.

Oropharyngeal candidiasis (OPC), often referred to as *thrush,* is caused by the yeast *Candida. C. albicans,* a common oral commensal organism, is the most frequent infecting species. OPC is also referred to as *candidiasis* (or the more correct but less commonly used term *candidosis*). The infection may extend into the esophagus, causing esophageal candidiasis.

Epidemiology and Etiology

Candida is a commensal fungus found in the oral cavity in up to 65% of healthy individuals with higher prevalence in healthy children and young adults.[26,27] *Candida* carriage increases in immunocompromised and hospitalized patients.[27] Even in the era of highly active antiretroviral therapy (AART) up to 80% of HIV-infected persons may demonstrate oral yeast colonization.[28] The organism is capable of transition to a pathogen causing symptomatic mucosal infections in association with predisposing host factors.[27] *C. albicans* is the predominant colonizing *Candida* species (70%-80%), but any of the non–*C. albicans* species such as *C. glabrata* and *C. tropicalis,* which may account for 5% to 8%, respectively, can be colonizers. Colonization rates are influenced by the severity and nature of the underlying medical illness and the duration of hospitalization, as well as age (highest in infants younger than 18 months of age and in adults older than 60 years of age). A variety of host and exogenous factors (Table 143-3) can lead to the transformation of asymptomatic colonization to symptomatic disease, such as oropharyngeal and esophageal candidiasis. *C. albicans* is the most common species causing all forms of mucosal candidiasis in humans. Less frequently, non–*C. albicans* species can be pathogenic and cause disease. These include *C. glabrata, C. tropicalis, C. krusei,* and *C. parapsilosis.*[28,29] *C. krusei,* although relatively uncommon, generally is recovered from mucosal surfaces of neutropenic patients with hematologic malignancies.[29] *Candida dubliniensis* has been identified in both HIV-infected and noninfected patients, and may cause ~15% of infections previously ascribed to *C. albicans.*[29] In patients with cancer, non–*C. albicans* species account for almost half of all *Candida* infections.

TABLE 143-3

Risk Factors for the Development of Oropharyngeal and/or Esophageal Candidiasis

Local Factors	Potential Mechanisms
Use of steroids and antibiotics	Suppression of cellular immunity and inhibition of phagocytosis by steroids, including chronic use of inhaled and topical steroids
	Alteration of endogenous oral flora by broad-spectrum antibiotics, especially when used with steroids, creates a milieu for proliferation of *Candida* species because of reduced environmental and nutritional competition
Dentures	Enhanced adherence of *Candida* species to the acrylic material of dentures, reduced saliva flow under surfaces of denture fittings, improperly fitted dentures, and poor oral hygiene provide a milieu conducive to the survival of microorganisms
Xerostomia caused by drugs (eg, tricyclic antidepressants and phenothiazine), chemotherapy, radiotherapy to the head/neck, and various diseases (eg, Sjögren's syndrome, HIV, and cancer of the head/neck), as well as bone marrow transplant recipients	Reduced dilutional and cleansing effect caused by low secretion rate and low pH in saliva: Saliva and mucosa secretions have defense factors, such as lactoferrin, sialoperoxidase, isozyme, histidine-rich polypeptide, secretory IgA antibodies, and specific anti-*Candida* antibodies, that help prevent adhesion and overgrowth of *Candida* species
Smoking	
Disruption of oral mucosa caused by chemotherapy and radiotherapy, ulcers, endotracheal intubation trauma, and burns	Oral mucositis induced by radiation and breaks in the physical barrier of the oral epithelium, which is protective against invasion by microorganisms; altered rate of mucosa regeneration by cancer chemotherapy, which increases vulnerability to infection

Systemic Factors	Potential Mechanisms
Drugs (eg, cytotoxic agents, corticosteroids, and immunosuppressants after organ transplant), omeprazole, and environmental chemicals (eg, benzene and pesticides)	Reduced immunity because of drug-induced neutropenia or cell-mediated immunity; potent inhibition of gastric acid by PPIs can facilitate the growth of *Candida* species; PPIs also can inhibit the cytotoxic effect of lymphocytes and reduce salivary secretion
Neonates or the elderly	Immature immune system of neonates who usually acquire infection during birth to a mother with vaginal candidiasis or from exposure to infected bottle nipples or to skin of adult caregiver
	Elderly—unclear if this is the direct effect of age per se or contribution from dentures or underlying comorbidity
HIV infection/AIDS	Depletion of CD4 T lymphocytes especially below 200-300 cells/mm^3 (0.2 × 10^9 to 0.3 × 10^9/L); anti-*Candida* protective mechanism of T lymphocytes at a mucosal level is unclear but can be caused by altered cytokines, especially interferon-γ, that inhibit transformation of *Candida* blastoconidia to the more invasive hyphal phase
Diabetes	Higher than normal numbers of *C. albicans* cultured from saliva of diabetic patients; can be related to the elevated glucose levels and reduced chemotactic factor in saliva, altered neutrophil function, and reduced saliva volume and flow
Malignancies (eg, leukemia and head/neck cancer)	Use of intensive radiotherapy and chemotherapy can disrupt oral mucosa and cause xerostomia; prolonged use of broad-spectrum antibiotics in neutropenic patients can alter the normal oral flora; because of the prolonged neutropenia, the principal immune defect, seen especially in leukemic patients, the initial oropharyngeal candidiasis can become systemic or invasive
Nutritional deficiencies (eg, iron, folate, and vitamins B1, B2, B6, B12, and C)	Can be related to dietary restriction or GI absorption problems; deficiencies can serve to enhance the pathogenic potential of the *Candida* inhabitants, alter host defense mechanisms, or change epithelial barrier integrity

AIDS, acquired immunodeficiency syndrome; GI, gastrointestinal; HIV, human immunodeficiency virus; IgA, immunoglobulin A; PPI, proton pump inhibitor.

Oropharyngeal candidiasis remains the most common opportunistic infection in patients with HIV disease, and it may be the first clinical manifestation of the HIV infection in the majority of untreated patients. OPC occurs in 50% to 90% of HIV-infected patients if the disease progresses to acquired immunodeficiency syndrome (AIDS).[26,28,29] The use of effective antiretroviral therapy has led to a significant reduction in the primary incidence and ultimately refractory disease. The absolute CD4 T-cell count is the primary risk factor for development of OPC with the greatest risk at CD4 T-cell levels <200 cells/mm^3 (0.2 × 10^9/L). Also, the HIV viral load is a predictor of OPC development; OPC increases with HIV viral loads >10,000 copies/mL (10 × 10^6/L). This finding correlates with the observation that initiation of antiretroviral therapy and subsequent increase in CD4 T-cell counts does not fully account for the decrease in OPC incidence.[28] Regardless of the CD4 T-cell count, or HIV viral load, OPC is predictive for the development of AIDS-related illnesses if left untreated.[26,29]

In non-HIV diseases, such as cancer, the incidence of OPC varies depending on the type of malignant neoplastic disease, level of immune suppression, and type and duration of treatment, but it is less common than in HIV-infected patients. OPC was initially reported in ~25% of patients with solid tumors and up to 60% in those with hematologic malignancies or bone marrow transplant recipients.[30] Rates of OPC have decreased significantly in these patients because of widespread use of antifungal prophylaxis. Incidence in other patient populations predisposed to OPC such as the hospitalized patient administered broad-spectrum antibiotics or denture and other oral appliance users is not well quantified. However, it does represent at-risk individuals where the clinical pharmacist has an important patient-care role.[27,30]

OPC can predispose patients to develop more invasive disease, including esophageal candidiasis.[30] The esophagus is the second most common site of gastrointestinal (GI) candidiasis. The prevalence of esophageal candidiasis increased mainly due to the emergence of AIDS, as well as the increased numbers of other severely immunocompromised patients, especially those with hematologic malignancies.[29] The mean incidence of esophageal candidiasis among HIV-infected patients is less than OPC and ranges from 15% to 20%.[29] The risk of esophageal candidiasis is increased in HIV-infected patients when the CD4 T-cell count has dropped below 100 to 200 cells/mm^3 (0.1×10^9 to 0.2×10^9/L), as well as in those with OPC.[30,31] However, the absence of OPC does not necessarily exclude the possibility of esophageal disease. Like OPC, the presence of esophageal candidiasis can help predict HIV disease progression and prognosis.[30] The incidence of esophageal candidiasis in non–HIV-infected immunocompromised patients is not well established. *C. albicans* is the most common cause of esophageal candidiasis, accounting for ~80% of cases, with the rest being caused by non–*C. albicans* species.[28] However, the widespread use of the azole agents for treatment and prophylaxis has led to an emergence of refractory infections that are more challenging to treat.

Pathogenesis and Host Defenses

The pathogenesis of OPC is most clearly elucidated in the setting of HIV infection. There appear to be several levels of immune defense against the development of OPC in HIV-infected persons, and they involve both systemic and local immunity. The primary line of host defense against *C. albicans* is cell-mediated immunity (CMI) at the mucosal surfaces, which is mediated by CD4 T cells.[26] The efficacy of the CD4 T cells is reduced when the number of cells drops below a protective threshold, and protection against infection becomes dependent on secondary or local immune mechanisms.[26,28] When the number of CD4 T cells drops too low, recruitment of these cells to the oral cavity is impaired. The CD4 T-cell count is the hallmark predictor for development of OPC. However, HIV viral load may have a stronger association with OPC than CD4 cell number.[28,32] The possibility that HIV plays a strong role in susceptibility to infection is supported by the observation that OPC is more common in HIV-infected persons than in those with similar immunosuppression, such as lymphoma and bone marrow transplant. When the primary line of defense fails, the secondary host defenses become crucial. These include the CD8 T cells, salivary cytokines, and other innate immune cells, such as the neutrophils, macrophages, and epithelial cells (with anti-*Candida* activity). Deficiencies or dysfunction in any of these can result in increased susceptibility to OPC. The problem with the CD8 T cells is caused more by a dysfunction of the microenvironment, specifically reduction in the E-cadherin adhesion molecule that promotes migration of the cells through mucosal tissues.[29] The role of humoral immunity by antibodies as a protective mechanism is unclear and controversial. The changeover of the role of *Candida* species from commensal to pathogenic in the human host usually occurs when breakdown in these host defenses occurs. The pathogenesis of OPC is still not completely understood. It is important to develop a better understanding of the pathogenesis and role of host defenses, including the mechanism of CD8 T-cell activity, reduced adhesion molecules, and whether other cofactors, such as HIV viral load, AART, and injection drug use, play a role. Immunotherapeutic modalities can then be developed to eliminate the susceptibility factors and significantly reduce OPC in the at-risk populations.

Significant differences exist in the virulence among *Candida* species in mucosal candidiasis. One virulence factor is the ability of the organism to adapt and survive in response to changes in the host environment.[28] The genes required for virulence are regulated in response to the environmental signals indigenous to the host environment (eg, temperature, pH, osmotic pressure, iron and calcium ion concentrations, oxygenation, and carbon and nitrogen availability). The ability of *C. albicans* to undergo reversible morphologic transition between the budding pseudohyphal and the more invasive hyphal growth forms is also a determinant of virulence, and genes are recognized to play a role.[26] Other virulence factors are the adhesive ability of *C. albicans* to epithelial cells and proteins and its ability to invade host cells by means of phospholipase and proteinase enzymes. This may be one of the factors leading to OPC in non–HIV-infected individuals. Other components of the pathogenesis in the absence of HIV are the ability of the *Candida* species to adhere to buccal epithelial cells.[33] This may be a key element in the development of OPC in patients with altered microflora, including those receiving broad-spectrum antimicrobial therapy.

Risk Factors

④ Several host and exogenous factors contribute to the ability of *Candida* species to cause infection (see Table 143-3). Local and systemic factors, as well as characteristics of the organism itself, can increase the susceptibility of an individual to *Candida* infections.[26] Endocrine disorders besides diabetes mellitus, such as hypothyroidism, hypoparathyroidism, and hypoadrenalism, also can predispose patients to *Candida* species overgrowth.

Patients with primary immune deficiencies such as lymphocytic abnormalities, phagocytic dysfunction, immunoglobulin A (IgA) deficiency, viral-induced immune paralysis, and severe congenital immunodeficiencies are also at risk for oropharyngeal candidiasis as well as disseminated candidiasis. Oral mucosal disease, such as lichen planus, can be preexistent causes of candidiasis. Smoking has been suggested as a predisposing risk factor. In many cases, multiple concurrent predisposing factors to candidiasis can exist, for example, xerostomia with mucositis and a break in the epithelial surface or immunosuppression, such as might occur in a leukemic patient receiving radiation and chemotherapy. The severity and extent of *Candida* infections increase with the number and severity of predisposing risk factors.[27]

Clinical Presentation and Diagnosis

Oropharyngeal candidiasis can manifest in several major forms (Table 143-4).[26,27] The clinical signs and symptoms of OPC and the locations of the lesions can be quite diverse (Table 143-5). A presumptive diagnosis of OPC usually is made by the characteristic appearance on the oral mucosa, with resolution of signs and symptoms after antifungal therapy. Pseudomembranous candidiasis, commonly known as *oral thrush,* is the classic and most common form seen in immunosuppressed and immunocompetent hosts. Erythematous and hyperplastic candidiasis and angular cheilitis occur less commonly in the HIV-infected population. Dysphagia, odynophagia, and retrosternal chest pain are common complaints of esophageal candidiasis, which is usually, but not always, accompanied by the presence of OPC. Clinical symptomatology, along with a therapeutic trial of antifungal, can provide a reliable presumptive diagnosis of esophageal candidiasis. If antifungal therapy does not lead to resolution, more invasive tests such as upper GI endoscopy can be undertaken.

TABLE 143-4

Clinical Classification of Oropharyngeal Candidiasis

Types	Population at Risk	Clinical Signs and Appearance
Pseudomembranous (thrush)	Neonates, patients with HIV or cancer, the debilitated elderly, patients on broad-spectrum antibiotics or steroid inhalers, patients with dry mouth from various causes, and smokers	Classic “cottage cheese” appearance, yellowish white, soft plaques (or milk curds) overlying areas of erythema on the buccal mucosa, tongue, gums, and throat; plaques are easily removed by vigorous rubbing but can leave red or bleeding sites when removed; lesions on the tongue dorsum give it a bald, depapillated appearance
Erythematous (atrophic)	Patients with HIV, patients on broad-spectrum antibiotics or steroid inhalers	Sensitive and painful erythematous mucosa with few, if any, white plaques; lesions are generally on the dorsal surface of the tongue or the hard palate, occasionally on the soft palate, but any part of the mucosa can be involved; appear as flat red patches on the palate or atrophic patches on the tongue dorsum with loss of papillae. Can be acute or chronic
Hyperplastic (candidal leukoplakia)	Smokers; uncommon in patients with HIV	Thick white and adherent keratotic plaques commonly seen on the buccal mucosa and lateral border of the tongue; can also be seen on the lips and the bottom of the mouth; plaques cannot be easily scraped off or only partially removed; this condition is distinct from oral hairy leukoplakia, and it can progress to severe dysplasia or malignancy
Angular cheilitis	Patients with HIV, denture wearers	Painful red, ulcerative, cracking, or fissuring lesion at one or both corners of the mouth because of an inflammatory reaction; usually lesions are small and rather punctate, but occasionally they can extend in a linear fashion from the angles onto the facial skin
Denture stomatitis (chronic atrophic)	Denture wearers who tend to be elderly and have poor oral hygiene	Red, flat lesions on the mucosa beneath the denture and extend right up to the denture border; more commonly located beneath a maxillary denture, although they can be encountered beneath a mandibular denture
Central papillary atrophy (median rhomboid glossitis)	Uncommon (<1% prevalence), males more commonly infected than females (3:1)	Rhomboid-shaped hypertrophic or atrophic plaque in the mid-dorsal tongue. Lesions may not resolve completely

HIV, human immunodeficiency virus.

TABLE 143-5

Clinical Presentation of Oropharyngeal and Esophageal Candidiasis

Oropharyngeal Candidiasis	Esophageal Candidiasis
General	**General**
The clinical features can be quite diverse (see Table 143-4)	This usually occurs as an extension of OPC; however, the esophagus can be the only site involved; the distal two-thirds, rather than the proximal one-third, is the most common site
Symptoms	**Symptoms**
Symptoms are diverse and range from none to a sore, painful mouth, burning tongue, metallic taste, and dysphagia and odynophagia with involvement of the hypopharynx	Typically, the symptoms are dysphagia, odynophagia, and retrosternal chest pain but can be asymptomatic in some patients; although rare, epigastric pain can be the dominant symptom
Signs	**Signs**
Signs are variable and can include diffuse erythema and white patches on the surfaces of the buccal mucosa, throat, tongue, or gums; constitutional signs are absent	Constitutional signs, including fever, occasionally occur; physical findings can range from a few to numerous white or beige plaques of variable size Plaques can be hyperemic or edematous, with ulceration in more severe cases Most advanced cases can occur with increased mucosal friability and narrowing of lumen Uncommon complications include perforation and aortic–esophageal fistula formation
Laboratory tests	**Laboratory tests**
Scraping of an active lesion for microscopic examination can help confirm the diagnosis (presence of pseudohyphae and budding yeast) but is usually not necessary Cultures are not necessary because isolation of *Candida* species does not distinguish between colonization and true infection; cultures can be taken in patients responding poorly to therapy to determine the infecting species and to predict likely drug resistance	The best test is upper GI endoscopy (more useful than barium swallow); helps exclude other causes of esophagitis (eg, viral, aphthous ulcers); diagnosis is confirmed by the histologic presence of *Candida* species in biopsy lesions taken during endoscopy Cultures to look for drug-resistant *Candida* species are warranted in patients who require endoscopy

GI, gastrointestinal; OPC, oropharyngeal candidiasis.

Treatment

Desired Outcomes

The primary desired outcome in the management of OPC is a clinical cure, that is, elimination of clinical signs and symptoms. Even when the patient is relatively asymptomatic, it is important to treat the initial episode of OPC to avoid progression to more extensive disease. In the most severe cases, the patient's quality of life can be impaired; this can result in decreased fluid and nutritional intake. Lack of appropriate treatment of OPC can lead to more extensive oral disease, especially in patients who are immunocompromised. The most serious complication of untreated OPC is extension of the infection to esophageal candidiasis which is more debilitating with greater impact on the patient's quality of life. Appropriate antifungal therapy should be initiated for both OPC and esophageal candidiasis. Preventing or minimizing the number of future recurrences of both types of candidiasis is an equally important outcome. The approach depends largely on the underlying predisposing conditions. Mycologic cure is not a necessary treatment outcome because it may not be feasible or realistic, given that *Candida* species exist commonly as part of the normal mouth flora.

Minimizing toxicities and drug-drug interactions of systemic antifungal agents and maximizing adherence by ensuring that the patient understands the importance of therapy and the directions to take the medication appropriately are important secondary outcomes of therapy.

General Approach to Treatment

The management of OPC should be individualized for each patient, taking into consideration the underlying immune status, other concurrent mucosal and medical diseases, concomitant medications, and exogenous infectious sources. Generally, topical therapy is used in mild forms of infections that have limited ability to spread. Systemic therapies are reserved for more moderate infection which may lead to dissemination of the infection.[27,28,34]

Whenever feasible, it is desirable to minimize all predisposing factors, such as administration of corticosteroids, chemotherapeutic agents, and antimicrobials, as well as to institute proper oral hygiene and resolve concurrent conditions, such as denture stomatitis. Selection of an appropriate antifungal agent for treatment of candidiasis requires consideration of several factors, including the patient's drug adherence, adequate saliva for dissolution of solid topical medications, risk of caries from sucrose- or dextrose-containing preparations, potential drug interactions, coexisting medical conditions (eg, liver disease), location and severity of the infection, and the need for long-term maintenance therapy.

⑤Topical antimycotic therapies should be the first choice for milder forms of infections.[34] The efficacy of antimycotic agents for OPC varies in different patient populations. Until the polyene antimycotic agents became available in the 1950s, gentian violet, an aniline dye, was used to treat OPC. Problems with gentian violet include fungal resistance, skin irritation, and especially the unaesthetic staining of the oral mucosa. In resource limited areas gentian violet remains a therapeutic option. Gentian violet solution of 0.00165% does not stain the oral mucosa and has potent antifungal activity.[35] Topical agents, such as nystatin and clotrimazole, are the standard of treatment for uncomplicated OPC and generally are effective for treatment in otherwise healthy adults and infants with no underlying immunodeficiencies. Topical agents are available in an assortment of formulations, including oral rinses (suspension), troches, powder, vaginal tablets, creams, and most recently as a mucoadhesive tablet[30,34,36] (Table 143-6).

TABLE 143-6

Therapeutic Options for Mucosal Candidiasis

Initial Episodes of OPC:[a] Treat for 7-14 Days	Common/Significant Side Effects
Clotrimazole 10 mg troche: hold 1 troche in mouth for 15-20 minutes for slow dissolution five times daily (B-2)	Altered taste, mild nausea, vomiting
Nystatin 100,000 units/mL suspension: 5 mL swish and swallow orally four times daily (B-2)	Mild nausea, vomiting, diarrhea
Miconazole 50 mg mucoadhesive buccal tablets 50 mg orally daily (A-1)	Diarrhea, headache, nausea, dysgeusia, upper abdominal pain, and vomiting
Fluconazole 100 mg tablets:[b] 100-200 mg orally daily (A-1)	GI upset, hepatitis not common

Itraconazole 10 mg/mL solution:[c] 200 mg orally daily (A-2)	GI upset, not common: hepatotoxicity, CHF, pulmonary edema with long-term use[d]
Posaconazole 40 mg/mL suspension: 400 mg orally daily with a full meal (A-2)	GI upset, fever, headache, increased hepatic transaminases not common
Fluconazole-Refractory OPC: Treat for ≥14 Days	
Itraconazole 10 mg/mL solution: 200 mg orally daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg orally twice daily (>40 kg), taken on empty stomach (A-3)	GI upset, rash, reversible visual disturbance (altered light perception, photopsia, chromatopsia, photophobia), increased hepatic transaminases, hallucinations, or confusion
Posaconazole 40 mg/mL suspension: 400 mg orally twice daily × 3 days, then 400 mg daily × 28 days (A-2)	See above
Amphotericin B 100 mg/mL suspension:[e] 1-5 mL swish and swallow orally four times daily (B-2)	Oral: nausea, vomiting, diarrhea with higher dose
Amphotericin B deoxycholate 50 mg injection: 0.3–0.7 mg/kg/day IV daily (B-2)	IV: fever, chills, sweats, nephrotoxicity, electrolyte disturbances, bone marrow suppression
Caspofungin 50 mg IV daily (B-2)	Fever, headache, infusion-related reactions (<5%) (eg, rash, facial swelling, pruritus, vasodilation), hypokalemia, increased hepatic transaminases, anemia, neutropenia
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 200 mg IV daily (B-2)	Similar to caspofungin
Esophageal Candidiasis:[a] Treat for 14-21 Days	
Fluconazole 100 mg tablets: 200-400 mg orally (3-6 mg/kg) daily (A-1)	See above
Echinocandin: see above (B-2)	See above
Amphotericin B deoxycholate 50 mg injection: 0.3-0.7 mg/kg/day IV daily (B-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg orally twice daily (A-3)	See above
Itraconazole 10 mg/mL solution:[c] 200 mg orally daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg orally twice daily (>40 kg) (A-3)	See above
Voriconazole IV and echinocandins (A-1): generally reserved for refractory cases	See above
Fluconazole-Refractory EC: Treat for 21-28 Days	

Itraconazole 10 mg/mL solution: 200 mg orally daily (A-2)	See above
Posaconazole 40 mg/mL suspension: 400 mg orally twice daily (A-3)	See above
Voriconazole 200 mg tablets: 200 mg orally twice daily (>40 kg), taken on empty stomach (A-3)	See above
Caspofungin 50 mg IV daily (B-2)	See above
Micafungin 150 mg IV daily (B-2)	Similar to caspofungin
Anidulafungin 100 mg IV on day 1, then 50 mg IV daily (B-2)	Similar to caspofungin
Amphotericin B deoxycholate: 0.3-0.7 mg/kg/day IV, or lipid-based amphotericin 3-5 mg/kg/day IV (B-2)	See above

CHF, congestive heart failure; GI, gastrointestinal; OPC, oropharyngeal candidiasis.

[a] Initial episodes of OPC can be adequately treated first with topical agents before resorting to systemic therapy (B-2), but systemic therapy is required for effective treatment of esophageal candidiasis. (A-2) Suppressive therapy is recommended for patients with frequent or severe recurrences (A-1).

[b] Fluconazole is more effective than ketoconazole (A-1).

[c] Solution is more effective than capsule (A-1); solution is better taken on an empty stomach.

[d] Suspension is not marketed; can be prepared extemporaneously by pharmacy.

[e] See discussion under onychomycosis.

Recommendation grades: Strength of recommendation: **A**—Both strong evidence for efficacy and substantial clinical benefit to support recommendation for use. *Should always be offered.* **B**—Moderate evidence for efficacy but only limited clinical benefit, to support recommendation for use. *Should generally be* offered. **C**—Evidence for efficacy is insufficient to support recommendation for or against use; or evidence for efficacy might not outweigh adverse consequences or cost of the treatment under consideration. *Optional.* **D**—Moderate evidence for lack of efficacy or adverse outcome supports a recommendation against use. *Should generally not be offered.* Quality of evidence: **1**—Evidence from at least one properly designed randomized, controlled trial. **2**—Evidence from at least one well-designed trial without randomization, from cohort or case-controlled analytic studies (preferably from more than one center), or from multiple time-series studies, or dramatic results from uncontrolled experiments. **3**—Evidence from opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees. (UR) Evidence currently unrated.

Topical agents require frequent applications because of the short contact time with the oral mucosa; the ideal contact time is 20 to 30 minutes. Sufficient saliva is needed to dissolve clotrimazole troches, and this can be problematic for patients with xerostomia. Also, the rough surface of the tablet can become irritating to the oral soft tissue. Troches also contain dextrose, which has cariogenic potential. Nystatin suspension might be a better choice for patients with xerostomia, but it is difficult to maintain adequate contact time with the oral mucosa. Some patients complain of the unpleasant taste of nystatin, which can cause nausea and vomiting; this is especially problematic in cancer patients experiencing chemotherapy-induced nausea. The high sucrose content of nystatin suspension is cariogenic in dentate patients, and it should be used with caution in diabetic patients.[27,30] Miconazole 50 mg mucoadhesive tablets are a buccal adherent miconazole product approved for the local treatment of OPC in adults and adolescents older than age 16 years.[37] This product offers the advantage of a once-daily formulation that is tasteless, odorless, and sugar free.[36] Topical creams, such as clotrimazole, ketoconazole, miconazole, and nystatin (usually mixed with a steroid), are more appropriate for application three times daily to the corners of the mouth in treating angular cheilitis, the inflammation, drying, and cracking of the corners of the mouth.[34]

Systemic therapy is necessary in patients with OPC that is refractory to topical treatment, those who cannot tolerate topical agents, have moderate-to-severe disease, and those at high risk for disseminated systemic or invasive candidiasis. Effective treatment of esophageal candidiasis generally requires the use of systemic antifungal agents. However, these agents have the disadvantage of producing more side effects (see Table 143-6) and drug-drug interactions (see Chapter 144, "Invasive Fungal Infections"). Fluconazole is inexpensive and generally well tolerated, and its absorption is unaffected by food or gastric acidity. Ketoconazole requires gastric acidity for absorption, which can be problematic and this agent is not recommended today with the availability of more effective triazoles. Itraconazole capsules also have the same absorption problem and are no longer recommended. In contrast, itraconazole solution has enhanced absorption and is best taken in a fasting state; in addition, the solution provides the benefit of both topical effects to the oral mucosa and systemic effects and is beneficial to patients with mucositis or swallowing problems. Whenever possible, it is generally beneficial to limit the use of systemic azole agents to prevent unnecessary drug exposure and to minimize the potential for occurrence of drug-resistant candidiasis, particularly from fluconazole resistance.

Oropharyngeal Candidiasis: Human Immuodeficiency Virus–Infected Patients

Treatment for initial or recurrent episodes of OPC should be started with topical agents, provided that clinical symptoms are not severe and that there is minimal risk of esophageal involvement.[29,34] Clinical responses with the resolution of signs and symptoms generally occur within 5 to 7 days of initiating treatment. Clotrimazole appears to be the most effective topical agent and demonstrates comparable clinical response rates with both fluconazole and itraconazole.[29,34] However, topical therapy is associated with more frequent relapses than with fluconazole.[31,34] This may be of limited clinical significance in patients receiving effective AART because of their decreased susceptibility to opportunistic infection. In practice, nystatin suspension is still used frequently in initial episodes of OPC, although it is the least effective agent and is associated with frequent treatment failures and early relapses, especially in patients with advanced HIV disease or neutropenia.[27,30] Miconazole mucoadhesive tablets 50 mg once daily (MMT) were non-inferior to clotrimazole troches 10 mg five times daily for the treatment of OPC in HIV-infected patients. Safety and tolerability was also similar between treatment groups.[37]

Systemic oral azoles should be reserved for use in the more severe episodes of OPC unresponsive to topical agents or in patients with concurrent esophageal involvement.[30,34] In clinical practice, fluconazole usually is the systemic azole agent of choice because of its proven efficacy, favorable absorption, safety, and drug-interaction profiles, and it is relatively inexpensive. Fluconazole is superior to ketoconazole and itraconazole capsules.[30,34] Fluconazole should be given 100 to 200 mg/day for 7 to 14 days.[34] A single dose of fluconazole 750 mg orally was as effective as fluconazole 150 mg orally for 14 days, which warrants further evaluation, given the potential advantages of adherence and cost-effectiveness.[38] Itraconazole oral solution with an improved absorption profile compared with the capsule formulation is as effective as fluconazole, with comparable clinical and mycologic response and relapse rates.[30,34] However, it carries a higher risk of drug interactions because it is a potent inhibitor of the cytochrome P450 enzymes, and it is associated with more nausea than fluconazole. Posaconazole is an extended-spectrum triazole with potent in vitro activity against both *C. albicans* and non–*C. albicans* species. It is equivalent to fluconazole in terms of efficacy, safety, and tolerability.[39] Posaconazole, itraconazole solution, and voriconazole are the azole alternatives to fluconazole in the management of moderate-to-severe OPC.[33] Other agents that are effective are amphotericin B and the echinocandins (caspofungin, micafungin, and anidulafungin). They are reserved for refractory OPC, however, because of their greater toxicity. They are also more expensive and are less convenient to use.

Oropharyngeal Candidiasis: Non-Human Immunodeficiency Virus–Infected Patients

This patient population includes patients with hematologic malignancy (eg, leukemias) or blood and bone marrow transplantation (BMT) with a long duration of neutropenia and chronic graft-versus-host disease, patients with solid tumors, patients with solid-organ transplants who are receiving immunosuppressive therapy, and patients with diabetes mellitus, as well as patients on prolonged courses of antibiotics or corticosteroids and the debilitated elderly.

Specific antifungal therapy can be unnecessary for asymptomatic patients at relatively low risk for disseminated candidiasis, such as those who are not granulocytopenic or who are expected to have a short duration of granulocytopenia.[34] Many of these infections will clear spontaneously after recovery of the granulocytes or discontinuation of antibiotic and/or immunosuppressive therapy. However, antifungal therapy usually is required for patients who have persistent infection or significant symptoms, usually pain, or who are granulocytopenic with a relatively high risk of fungal dissemination. Topical agents first can be given a therapeutic trial depending on the severity of infection and the degree of immunosuppression. Although both nystatin and clotrimazole can be effective in treating OPC, nystatin suspension does not effectively reduce the incidence of either oropharyngeal or systemic *Candida* infections in immunocompromised patients receiving chemotherapy or radiation; its use often is associated with treatment failures and early relapses.[34] Clotrimazole appears to be more effective in reducing colonization and treating acute episodes in cancer patients who are immunocompromised. MMTs were superior to miconazole oral gel in patients with head and neck cancer in achieving a complete response to therapy.[40] MMT has not been studied against clotrimazole in this patient population specifically but is approved for use in adults with OPC.

Topical therapy with clotrimazole or nystatin for 7 days is usually adequate for treating mucocutaneous candidiasis in most solid-organ transplant patients.[30] Use of topical therapy will reduce the number of systemic drugs that these patients receive and hence minimize the risk of drug-drug interactions. Failure to respond to topical agents warrants the use of fluconazole. Low-dose amphotericin B solution as "swish and swallow" (100 mg/mL, 1 mL four times daily) for 7 to 10 days is reserved for the unusual cases of treatment failure as it is not readily available and requires compounding.

Patients who develop OPC because of prolonged antibiotic use or aerosolized corticosteroids use can be managed successfully by discontinuation of the offending agent, and the infection usually will resolve. If there is a strong desire to treat because of discomfort or need to hasten symptom resolution or an inability to stop the offending agent, therapy with a topical agent, either MMT, clotrimazole, or nystatin, is effective in most cases. The advantage of systemic azoles is the convenience of less frequent dosing. Symptoms usually improve in 3 or 4 days. Infants should be given smaller amounts more frequently (eg, nystatin 100,000 units every 2-3 hours) to ensure better contact time. For denture-related OPC, or candidal stomatitis, effective therapy requires treatment of both the mouth and the dentures to avoid relapse. The dentures must be brushed vigorously and disinfected every night by soaking in antiseptic solution, such as chlorhexidine gluconate 0.25% or a commercial denture disinfectant product.[30,34] Topical antifungal therapy of the oral cavity is required. Consistent proper oral hygiene and care of the dentures can help prevent relapse.

Systemic azole agents are used for treating OPC in patients who have failed or who are unable to take topical therapy.[30,34,39] The preceding discussion on the relative efficacy of fluconazole, itraconazole, and ketoconazole in HIV-infected patients can be extrapolated to the non–HIV-infected population. Oral fluconazole 100 to 200 mg daily is used more commonly because of more extensive experience with its use, and it is more effective and has a more favorable absorption and side-effect profile compared with other available azoles.[34] If the oral route is not feasible for reasons such as severe chemotherapy-induced mucositis, fluconazole can be administered IV. In patients unresponsive to azoles, IV amphotericin B in relatively low doses of 0.1 to 0.3 mg/kg/day can be tried.[34] Because of the higher risk for dissemination in patients who are severely neutropenic (<100 neutrophils/mm^3 [0.1 × 10^9/L]) or clinically unstable (hypotensive or febrile), some clinicians prefer to initiate therapy with IV amphotericin B at 0.6 mg/kg/day, with therapy continued until the neutropenia has resolved, or an echinocandin.[34] The echinocandins caspofungin, micafungin, and anidulafungin are all effective for the treatment of OPC, thus offering other options, with fewer adverse effects in the patient with refractory disease.[34]

Esophageal Candidiasis: Human Immunodeficiency Virus–Infected Patients

⑥Treatment of esophageal candidiasis has not been as well studied as OPC. Because of the significant morbidity of esophageal candidiasis and the absence of evidence supporting the efficacy of topical antifungals, treatment requires systemic antifungal agents.[26,28] Fluconazole is superior to ketoconazole and itraconazole capsules with respect to endoscopic cure and clinical response and usually produces a more rapid onset of action and resolution of symptoms. Fluconazole is as effective as itraconazole solution, with reported response rates of >80% to 90%.[31,34] However, itraconazole solution causes more nausea and drug interactions because of inhibition of the cytochrome P450 enzymes. Amphotericin B, voriconazole, posaconazole, and the echinocandins are also effective in esophageal candidiasis, but they are generally reserved for patients with advanced or inadequately controlled HIV disease where the candidiasis tends to recur or becomes refractory to azole therapy.[41–43]

Esophageal Candidiasis: Non-Human Immunodeficiency Virus–Infected Patients

As in the case of HIV-infected patients, treatment of esophageal candidiasis requires systemic therapy. Patients can be started on oral fluconazole 200 to 400 mg/day for 14 to 21 days.[34] Higher fluconazole doses (up to 400 mg/day) have been suggested for patients with severe symptoms or those who are neutropenic.[44] Other agents recommended if fluconazole is not an option are an echinocandin or IV amphotericin B at 0.3 to 0.7 mg/kg. Itraconazole solution, posaconazole, and voriconazole are effective alternatives that may be considered for those not responding adequately to fluconazole. An echinocandin or IV amphotericin B may be selected over fluconazole for initial therapy in neutropenic patients who present with severe symptoms or who are at high risk for dissemination of *Candida* species, such as those receiving other aggressive immunosuppressive therapy (eg, corticosteroids, total-body irradiation, or antithymocyte globulin) and who have documented evidence of esophageal candidiasis or who have failed an initial empirical trial of oral nonabsorbable agents or systemic azoles.[34] Therapy should be continued at least until the neutropenia resolves. For patients whose symptoms have resolved and who are afebrile and clinically stable, therapy should be discontinued, and the patients should be monitored closely for infection recurrence. In high-risk patients, particularly those with persistent fever and neutropenia, the potential presence of clinically occult, diffuse GI or disseminated candidiasis should be considered. The echinocandins and newer azole agents (voriconazole and posaconazole) offer less toxic alternatives or oral agents and are preferred in patients who are intolerant of amphotericin B deoxycholate or who have preexisting renal impairment.[30,44,45]

Antifungal-Refractory Oral Mucosal Candidiasis

Treatment failure is generally defined as persistence of signs and symptoms of OPC or esophageal candidiasis after an appropriate trial of antifungal therapy.[29] Treatment of refractory oral mucosal candidiasis is frequently unsatisfactory, and clinical response is usually short-lived, with rapid and periodic recurrences. The key risk factors for occurrence of refractory candidiasis are advanced stage of AIDS with low CD4 cell counts (<50 cells/mm^3 [0.05×10^9/L]) and repeated or prolonged courses of various systemic antifungal agents, in particular systemic azoles.[30,34] Frequent or prolonged use of fluconazole can be associated with fluconazole-refractory candidiasis because of selection of more resistant non–*C. albicans* species. An important initial management strategy is to assess and optimize the antiretroviral therapy of the patient with refractory OPC to help improve the immune function. With the widespread use of AART, fluconazole-refractory OPC is now less commonly encountered. It is also important to identify and rectify potentially correctable causes of clinical failures of mucosal candidiasis, such as poor drug adherence, adequate dosing, reduced drug absorption associated with hypochlorhydria, and drug–drug interactions.

Few controlled studies have assessed the effectiveness of antifungal agents. Doubling of the fluconazole dosage to 400 or 800 mg/day can be effective in some patients with infection caused by *Candida* species of intermediate resistance, although the response may be only transient.[31] Fluconazole oral suspension can be beneficial in some patients because of increased salivary concentrations obtained when the suspension is taken with the swish and swallow technique.[34] Patients with fluconazole-refractory mucosal candidiasis can be treated with itraconazole oral suspension because it can be effective in 64% to 80% of patients; however, the benefit is short-lived if chronic suppressive therapy is not maintained.[29,34] Posaconazole suspension was successful in ~74% of patients with refractory oral or esophageal candidiasis; voriconazole may also be efficacious in these patients. Amphotericin B oral suspension is another alternative for azole-refractory patients.[31,34] It has broad-spectrum activity against many fungal species and low likelihood of *Candida* species resistance. Amphotericin B suspension is no longer available commercially in the United States, but it can be prepared extemporaneously by the pharmacy.[46]

IV amphotericin B deoxycholate has been the alternative for patients with endoscopically proven disease who have failed fluconazole or itraconazole therapy. Patients with severe disease unresponsive to other agents require IV amphotericin B 0.3 to 0.7 mg/kg/day for 7 to 10 days to achieve clinical response; higher dose or longer treatment duration can be needed in more severe disease.[31,34] After response, suppressive therapy with amphotericin B is required to increase disease-free intervals. Patients who fail to respond to amphotericin B and require >1 mg/kg/day might be candidates for liposomal amphotericin B preparations because of renal and/or bone marrow toxicities, although at a markedly higher cost. Flucytosine usually is not used as monotherapy because of rapid development of resistance but can be used in combination with an azole or amphotericin B.[31] Less toxic agents that are also effective are voriconazole and the echinocandins.[44,45] Voriconazole, a triazole antifungal available in both oral and IV preparations, is as effective as fluconazole for esophageal candidiasis, and has shown success in treatment of fluconazole-refractory disease.[43] However, voriconazole has more side effects and multiple pharmacokinetic drug interactions compared to fluconazole.[43] Caspofungin is the first of the echinocandins to be approved for esophageal candidiasis. Micafungin and anidulafungin have been approved for this indication. All three echinocandins have similar efficacy and tolerability profile as fluconazole, although higher relapse has been reported with caspofungin and anidulafungin compared with fluconazole.[34,45] Because the echinocandins require IV administration and are expensive, they are primarily used in patients who are refractory to the triazoles or have serious triazole-related adverse effects. As a class, the echinocandins have a favorable adverse effect profile. They are less toxic than amphotericin B (see Table 143-6) and have less impact on the cytochrome P450 enzymes than either itraconazole or voriconazole. Immunomodulation with adjunctive granulocyte-macrophage colony-stimulating factor and interferon have been used for refractory oral candidiasis in limited numbers of patients.[34]

Antifungal Prophylaxis

⑦Ensuring that the HIV-infected patient is receiving appropriate antiretroviral therapy to enhance the immune system is perhaps the most important measure in preventing future episodes of mucosal candidiasis (oropharyngeal, esophageal, and vulvovaginal).[34] Initial success of treatment often is followed by symptomatic recurrences, especially in patients with advanced or poorly controlled HIV disease. Long-term suppressive therapy with fluconazole is effective in preventing recurrences or new infections of OPC in HIV disease and in patients with cancer.[34] However, the indications for antifungal prophylaxis and the best long-term management strategy still have not been well established. Fluconazole does not provide complete protection, and breakthrough infections can occur.[31] The reduced risk of recurrence of OPC does not improve survival. In addition, chronic exposure to azole therapy might lead to the development of refractory disease or emergence of azole resistance.[34] However, in a randomized trial of continuous versus episodic fluconazole therapy, continuous therapy did not result in a higher rate of refractory OPC or esophageal disease.[47] HIV specialists do not recommend primary or secondary prophylaxis for OPC.[31] The rationale includes effectiveness of therapy for acute episodes of OPC, low incidence of serious invasive fungal disease, low mortality associated with mucosal candidiasis, potential for drug interactions, potential for emergence of drug resistance, and the prohibitive long-term cost of prophylaxis.

⑧The decision to use secondary prophylaxis should be individualized for each patient. Secondary prophylaxis can be considered in patients with multiple recurrent episodes of symptomatic OPC or when the disease is sufficiently severe and affecting the quality of life.[31] Patients with a history of one or more episodes of documented esophageal candidiasis and a CD4 T-cell count still <200 cells/mm^3 (0.2 × 10^9/L) despite being on AART are candidates for secondary prophylaxis. Oral fluconazole 100 mg three times weekly is the regimen recommended by the Infectious Diseases Society of America for patients deemed in need of chronic suppressive therapy.[22] Itraconazole solution 200 mg daily orally is an alternative as suppressive therapy for OPC.[34]

Patients with malignant neoplastic diseases who are receiving irradiation, cytotoxic, and/or immunosuppressive therapy are at high risk for fungal infections in addition to bacterial and viral infections. Prophylaxis of *Candida* infection is controversial, and the results of studies have been conflicting and difficult to evaluate. In the hematopoietic stem cell transplant (HSCT) population, fluconazole prophylaxis is recommended prior to engraftment. Cross-resistance to other azoles may occur among *Candida* species; this should be a treatment consideration in a patient who develops a breakthrough fungal infection. Micafungin is an alternative to fluconazole prophylaxis of candidiasis.[48] The value of antifungal prophylaxis in these patients needs to be considered in the broader context of not only reducing colonization and the risk of superficial candidiasis but also, more importantly, reducing the risk for invasive candidiasis and improving survival. Management of these infections in this patient population is discussed further in Chapter 145, “Infections in Immunocompromised Patients.”

Evaluation of Therapeutic Outcomes

Efficacy end points for oropharyngeal and esophageal candidiasis include rapid relief of symptoms and prevention of complications without early relapse after completion of the course of therapy.[31,34] Sterilization of the oral cavity is not a feasible end point because mycologic eradication is rarely achievable, especially in HIV-positive patients. Symptomatic relief of presenting signs and symptoms (see Table 143-5) generally occurs within 48 to 72 hours of starting therapy, with complete resolution by 7 to 10 days. Patients should be advised about the time course and told to return for reassessment when signs and symptoms recur. It is usually unnecessary for the patient to be reassessed soon after finishing the treatment course. However, HIV patients should be questioned and examined for the occurrence of mucosal candidiasis as part of their regular follow-up. The frequency of monitoring can be more often in neutropenic patients because of concern for dissemination of candidiasis. During the period of neutropenia, temperature should be monitored daily, as well as signs of dissemination.

Efficacy of the antifungal agent is partly influenced by patient adherence to the medication regimen. Patients must be counseled on proper administration and dosing, in particular for topical agents (Table 143-7).[44] Safety end points include monitoring for occurrence of the relevant drug side effects and drug interactions (see Table 143-6). Mild GI intolerance can occur with topical therapy, but serious adverse effects are rare. It is prudent to monitor for hypersensitivity reactions, especially rash and pruritus that might occur with any medication. GI intolerance is more associated with the oral azoles. Hepatotoxicity can occur when azole therapy is prolonged beyond 7 to 10 days or high doses are used. Periodic monitoring of liver enzymes (alanine transaminase and aspartate amino-transferase) should be considered, especially if prolonged therapy (longer than 21 days) is anticipated. Patients who are receiving IV amphotericin B require daily monitoring by a pharmacist.

TABLE 143-7

Patient Counseling Tips for Managing Oropharyngeal Candidiasis

1. Clean the oral cavity prior to administering the topical antifungal agent. Daily fluoride rinses can help reduce the risk of caries when using an agent containing sucrose or dextrose.
2. Use the topical antifungal agent after meals, as saliva flow and mouth movements can reduce the contact time.
3. Troches should be slowly dissolved in the mouth, not chewed or swallowed whole, over 15-20 minutes, and the saliva swallowed.
4. Suspension should be swished around the mouth in the oral cavity to cover all areas for as long as possible, ideally at least 1 minute, then gargled and swallowed.
5. Remove dentures while medication is being applied to the oral tissues.
6. Use a suspension or buccal mucoadhesive tablet instead of a troche if xerostomia is present; if a troche is preferred, the patient should rinse or drink water prior to dosing. For xerostomia, suggest nonpharmacologic measures for symptomatic relief (eg, ice chips, sugarless gum or hard candy, citrus beverages).
7. Dentures should be removed and disinfected overnight using an antiseptic solution (eg, chlorhexidine 0.12%-0.2%). Disinfect oral tissues in addition to dental prosthesis.
8. Complete treatment course even though symptomatic improvement can occur in 48-72 hours.
9. Maintain good oral hygiene. Brush teeth daily (twice daily) and floss, rinse mouth, or brush teeth after eating sweets.
10. Stop smoking; avoid alcohol.

Data from reference 42.

MYCOTIC INFECTIONS OF THE SKIN, HAIR, AND NAILS

Superficial cutaneous mycoses affect up to 20% to 25% of the population globally.[49] The usual pathogens are the dermatophytes classified by genera: *Trichophyton*, *Epidermophyton*, and *Microsporum*.[50] Less frequently infection is caused by nondermatophyte fungi (eg, *Malassezia furfur*) and *Candida* species. Dermatophytes can penetrate keratinous structures of the body and therefore infections are limited to hair, nails, and skin. These infections affect both males and females and all races. Reservoirs of mycotic infections include humans, animals, and soil.[50,51] Individuals can develop an infection if they come in contact with a reservoir in addition to having a conducive environment for mycotic growth (ie, moist conditions). Risk factors for the development of an infection include prolonged exposure to sweat or soaking in water, maceration, intertriginous folds, sharing personal belongings such as combs, and close living quarters (dormitories, barracks).[51]

Mycotic infections of the skin have a classic appearance that consists of a central clearing surrounded by an advancing red, scaly, elevated border, also referred to as an “active” border.[52] The central clearing of the lesion may distinguish dermatophytoses from other skin eruptions such as psoriasis or lichen planus that have a more uniform inflammatory presentation.[52] Infections of the nail can appear chalky and dull yellow or white and become brittle and crumbly.

Diagnosis usually is based on patient history, as well as the physical examination.[53,54] Diagnostic tests include direct microscopic examination of a specimen after the addition of KOH or fungal cultures. The KOH test is quick, inexpensive, and easy to perform, whereas cultures are more expensive and take longer to obtain results. Diagnostic tests are recommended when systemic therapy is likely to be prescribed.[53,54]

⑨ A general approach to treatment of superficial mycotic infections includes keeping the infected area dry and clean and limiting exposure to the infected reservoir. Topical agents generally are considered to be first-line therapy for infections of the skin. Oral therapy is preferred when the infection is extensive or severe or when treating tinea capitis or onychomycosis.[55,56] Table 143-8 lists specific treatments for each mycotic infection. Superficial mycotic infections are categorized by the pattern and site of infection.[50] The most commonly occurring infections in North America are detailed in the following sections.

TABLE 143-8

Treatment of Mycoses of the Skin, Hair, and Nails

	Topical[a,b]	Oral Regimen[c]
Tinea pedis	Butenafine, daily Sertaconazole, twice daily Luliconazole, daily Naftifine cream daily, gel daily	Fluconazole 150 mg 1 per week × 1-4 weeks
Tinea manuum	Ciclopirox, twice daily	Ketoconazole 200 mg daily × 4 weeks
Tinea cruris	Clotrimazole, twice daily Luliconazole, daily Naftifine cream, daily	Itraconazole 200-400 mg/day × 1 week
Tinea corporis	Econazole, daily	Terbinafine 250 mg/day × 2 weeks
	Haloprogin, twice daily	
	Ketoconazole cream, daily Luliconazole daily	
	Miconazole, twice daily	
	Naftifine cream, daily	
	Oxiconazole, twice daily	
	Sulconazole, twice daily	
	Terbinafine, twice daily	
	Tolnaftate, twice daily	
	Triacetin cream, solution, three times daily	
	Undecylenic acid, various preparations: apply as directed	
Tinea capitis	Shampoo only in conjunction with oral therapy or for treatment of asymptomatic carriers	Terbinafine 250 mg/day × 4-8 weeks

Tinea barbae	Ketoconazole twice weekly × 4 weeks	Ketoconazole 200 mg daily × 4 weeks
	Selenium sulfide daily × 2 weeks	Itraconazole 100-200 mg/day × 4-6 weeks
		Griseofulvin 500 mg/day × 4-6 weeks
Pityriasis versicolor	Clotrimazole, twice daily	Ketoconazole
	Econazole, daily	
	Haloprogin, twice daily	Fluconazole
	Ketoconazole, daily	
	Miconazole, twice daily	Itraconazole 200 mg daily × 3-7 days
	Oxiconazole cream only, twice daily	
	Sulconazole, twice daily	
	Tolnaftate, three times daily	
Onychomycosis	Ciclopirox 8% nail lacquer: apply solution at night for up to 48 weeks (fingernails and toenails) Efinaconazole 10% topical solution daily for 48 weeks (toenails) Tavaborole 5% topical solution daily for 48 weeks (toenails)	Terbinafine 250 mg/day × 6 weeks (fingernail), 12 weeks (toenail) Itraconazole 200 mg twice daily x 1 week/month for 2 months (fingernail); 200 mg daily x 12 weeks (toenail) Fluconazole 50 mg daily or 300 mg once weekly for ≥6 months (fingernail) or 12 months (toenail)

[a] Other products are available, including combination products.

[b] Length of therapy depends on mycotic sensitivity and severity of infection.

[c] Only capsule formulation studied; give with food for increased absorption.

Tinea Pedis

Tinea pedis is the most common dermatophytoses (affecting ~70% of adults). It is better known as "athlete's foot" and occurs in hot weather, with exposure to surface reservoirs (locker room floors), and with use of occlusive footwear.[51] Tinea pedis has three common presentations. The most common is the interdigital form which is characterized by fissuring, maceration, and scaling of the spaces between the toes (most frequently the fourth and fifth toes). Patients often complain of itching and burning. The "moccasin-like" distribution presentation is usually caused by *Trichophyton* *rubrum*. In this form the plantar surface becomes chronically scaly and thickened with accompanying erythema of the soles, heels, and sides of the foot. The third presentation, vesiculobulous tinea pedis, is characterized by the formation of vesicles, pustules, and occasionally bullae typically on the soles of the foot. Contact dermatitis, pustular psoriasis, and eczema would be in the differential diagnosis. Disruption of skin integrity with tinea pedis is a risk factor for streptococcal cellulitis as a complication. Treatment with topical therapy for 2 to 4 weeks often is adequate for mild infections; however, severe infections or involvement of the nails require oral therapy[51] (see Table 143-8). Recurrence of infection occurs in up to 70% of individuals especially if there is concomitant onychomycosis. Prolonged treatment with either topical or systemic therapy may be required.[50,55] Other nonpharmacologic measures such as disinfecting footwear, avoidance of walking barefoot in public places, controlling hyperhidrosis, wearing absorbent socks, and nonocclusive shoes should be advised.

Tinea Manuum

Tinea manuum is a superficial fungal infection of one or infrequently both hands, and can involve the feet (tinea pedis). The infection presents with dry and hyperkeratotic palmar surface of the hand. The fingernails, when involved, may present with vesicles and scaling. Contact dermatitis, eczema, psoriasis, and callus formation should be in the differential diagnosis. Treatment of this infection is similar to tinea pedis (see Table 143-8). Emollients that contain lactic acid also can be useful.[51] Relapse or recurrence is frequent especially if tinea pedis or onychomycosis is present.

Tinea Cruris

Tinea cruris is an infection of the proximal thighs and buttocks.[56] It is referred to as “jock itch” and is more common in males. Tinea cruris and tinea pedis often occur concurrently. High humidity and warm temperatures along with wet or tight-fitting clothes contribute to the development of tinea cruris. The scrotum and penis often are spared from infection. The lesions are red, scaling with raised borders. Pustules or vesicles and maceration are usually found along the active border. Itching and burning are the most common patient complaint. The differential diagnosis would include candida infection, erythrasma, mechanical intertrigo, psoriasis, and seborrheic dermatitis.[52] Treatment with topical therapy is recommended and should continue for 1 to 2 weeks after symptom resolution. Severe infections can require oral therapy (see Table 143-8). Relief of pruritus and burning can be facilitated with short-term (2 or 3 days) topical steroids (2.5% hydrocortisone).[51] The feet of the patient should also be examined as a source of infection. Nonpharmacological measures such as keeping the area dry or avoiding prolonged exposure to moisture are important patient counselling points.

Tinea Corporis

Tinea corporis, also known as ringworm, is an infection of the glabrous skin of the trunk, extremities, or face.[52] Lesions of tinea corporis may be singular or multiple and appear as round, scaly lesions with central clearing and a raised border with sharp margination. The border may exhibit pustules. The degree of pruritis is variable. The differential diagnosis includes nummular eczema, contact dermatitis, psoriasis, pityriasis rosea, tinea versicolor, granuloma annulare, and Lyme disease.[52] Prior use of topical corticosteroid preparations may alter the appearance such that the central clearing and raised borders are no longer apparent impacting diagnosis. Diagnosis should be confirmed with KOH examination of skin scrapings of the edge of the lesion. Therapy is similar to that for tinea pedis, tinea manuum, and tinea cruris (see Table 143-8). If the infection is widespread, systemic antifungal therapy may be necessary.

Tinea Capitis

Tinea capitis is a mycotic infection involving the scalp, hair follicles, and adjacent skin that primarily affects children.[57,58] Treatment should consist of oral therapy, as well as the cleaning of combs and brushes, which can be contaminated (see Table 143-8). Daily shampooing is recommended for removal of scales. Some children and adults can be asymptomatic carriers, thereby facilitating spread of the infection.[58] Terbinafine had the highest cure rates at 75%-78% when compared with griseofluvin, ketoconazole, itraconazole, and fluconazole.[59] Family members who culture positive for *Trichophyton tonsurans* should be treated with an antifungal shampoo (eg, ketoconazole, selenium sulfide, or povidone-iodine).[58]

Tinea Barbae

Tinea barbae affects the hairs and follicles of beards and mustaches.[58] Treatment is similar to that for tinea capitis (see Table 143-8). Removal of the beard or mustache is recommended.[51]

Pityriasis Versicolor

Hyper- and hypopigmented scaly patches characterize pityriasis versicolor, which is also known as *tinea versicolor*. It is caused by yeasts of the *Malassezia* genus that, with the exception of *Malassezia pachydermatis*, are all lipophilic. The seborrheic areas (scalp, face, back and front of the trunk) of the human body are always colonized by one or more *Malassezia* spp., such as *M. globosa*, *M. sympodialis*, *M. sloffiae*, and *M. restricta* are the most common colonizers; *M. globosa* and *M. furfur* are most frequent clinical infection isolates. The lesions are found on the trunk, face, and extremities.[50] It is more common in adults and in areas with tropical ambient temperatures. Topical treatment usually is adequate unless there is extensive involvement, recurrent infections, or failure of topical therapy.[60] Ketoconazole 2% shampoo was significantly more effective than selenium sulfide 2.5% shampoo (89% vs 35% cure rate).[60] Recurrence of infection after cessation of treatment may be as high as 60% in the first year and 80% the second year. Suppressive maintenance therapy either orally or topically may be used in these cases.[49]

Onychomycosis (Tinea Unguium)

Onychomycosis is a fungal infection of the nail apparatus and is the most common single cause of nail dystrophy, affecting up to 8% of the general population and accounting for up to 50% of all nail problems.[60–63] Onychomycosis more commonly affects the toenails (2%-14% of adults), ~4 to 19 times more frequently than fingernails, with prevalence increasing with age.[62] This can be because of the slower growth of toenails (three times slower than fingernails), making it easier for fungi to establish infection. Onychomycosis has a significant impact on quality of life, both functional and psychosocial. In addition, the affected nails can disrupt the integrity of the surrounding skin, potentially increasing the risk of secondary bacterial infections.[62]

Onychomycosis is due to infection by dermatophytes (tinea unguium), yeasts, and nondermatophyte fungi.[64] Dermatophytes are the most frequent causes of onychomycosis (~90% in toenail and ~50% in fingernail infections).[65] The dermatophytes responsible for causing >90% of cases of onychomycosis are *Trichophyton rubrum* (71%) and *Trichophyton mentagrophytes* (20%).[57,58] Less common fungi causing onychomycosis are the nondermatophytic molds (2.3%-11%) and yeasts (5.6%). *C. albicans* is the most commonly isolated yeast and typically affects fingernails rather than toenails.[60,66] Risk factors for dermatophytic onychomycosis are increasing age (especially older than 40 years), family history and genetic factors, immunodeficiency (eg, HIV, renal transplant, immunosuppressive therapy, and defective polymorphonuclear chemotaxis), diabetes mellitus, psoriasis, peripheral vascular disease, smoking, prevalence of tinea pedis, frequent nail trauma, and sporting activities such as swimming.[66,67] These risk factors also appear to apply to recurrence of onychomycosis. Mold onychomycosis does not seem to be associated with systemic or local predisposing factors, but there is a risk of systemic dissemination in immunosuppressed patients.[66] *Candida* onychomycosis seems to always occur in immunosuppressed patients.[66]

Onychomycosis can present in four or five different major clinical forms, of which lateral distal subungual onychomycosis is the most common type.[60,66,68] In distal subungual onychomycosis, the nail plate, the nail bed, and, in advanced cases, the matrix are all affected, and *T. rubrum* is the most common etiologic cause. The worst case of onychomycosis is progression of the infection to total dystrophic onychomycosis, characterized by almost complete destruction of the nail plate. White superficial onychomycosis is usually caused by *T. mentagrophytes*, where the infection is localized to the surface of the nail plate. In proximal subungual onychomycosis, the fungi (usually *T. rubrum*) invade the nail through the proximal nail fold and spread to the nail plate and matrix. Although proximal subungual onychomycosis is relatively uncommon in the general population, it occurs most frequently in severely immunocompromised patients and is often considered a marker for AIDS.[66,68] Because of the multifactorial etiology of onychomycosis, it is important to differentiate onychomycosis from other causes of nail dystrophies so that the patient receives appropriate therapy and is not subjected to prolonged treatment with unnecessary drugs. Besides clinical history and physical examination, proper diagnosis of onychomycosis can include the combination of direct microscopy of scrapings from the appropriate nail area to look for fungal hyphae and fungal cultures, and, if necessary, histologic examination.[62,69,70] Table 143-9 provides a differential diagnosis for fungal nail diseases.[71]

TABLE 143-9

Differential Diagnosis of Fungal Nail Infections

Diagnosis	Features Consistent with Diagnosis
Psoriasis	Nail pitting, rash elsewhere on body, family history of psoriasis
Lichen planus	Nail atrophy, scarring at proximal aspect of the nail
Periungual squamous cell carcinoma	Single nail affected, pain, warty nail fold change, or ooze from the edge of nail
Yellow nail syndrome	Multiple nails turn yellow, grow slowly, increased longitudinal and transverse curvature, intermittent pain and shedding, associated with chronic sinusitis, bronchiectasis, lymphedema
Trauma	Single nail affected, homogeneous alteration of nail color and altered shape of nail

Treatment

General Approach

In general, onychomycosis of the toenail is more difficult to treat than fingernails, requires longer treatment duration, and is associated with a higher recurrence. The treatment options for onychomycosis include oral and topical therapies, mechanical or chemical nail avulsion, or a combination of these. Onychomycosis merits proper assessment and treatment consideration because it is a debilitating disease and can exert a negative impact on quality of life (eg, cosmetic and psychosocial effects, pain, discomfort, and decreased ambulation).[62,64,66,72] It is reasonable to not treat persons with minimal toenail involvement and no associated symptoms.[71] Although definitive data are lacking regarding the risk of progression of untreated disease, it can lead to complications such as cellulitis or reduced mobility, which can further compromise peripheral circulation in those with diabetes or peripheral vascular disease; additionally, infected nails can serve as a source of transmission of fungi to other areas of the body, as well as to other people, such as close household contacts, or in communal bathing places.[63,64,66,72,73] Treatment decisions should be made on an individual basis. The primary end point of treatment is eradication of the organism, with secondary end points being clinical cure and improvement.[63] Assessment of clinical success (cure or improvement) requires follow-up for several months after the end of treatment because of the slow growth rate of nails, especially toenails (1 mm/month).[62,66] Successful eradication of the fungus does not always result in normalization of the nails because they can have been dystrophic prior to infection. This can cause patient dissatisfaction, especially if this is not explained before starting treatment.[68] There are several factors that must be taken into account on a patient-by-patient basis to ensure appropriate treatment decisions (Table 143-10). The impact of patient adherence on the success of treatment cannot be overemphasized. Patients need to be educated about their disease, expectations of treatment, and prevention of recurrence, and various strategies have been suggested to improve treatment success.[70]

TABLE 143-10

Factors That May Impact Treatment Decisions and Outcomes

- Type and severity of onychomycosis
- Causative organism—dermatophyte vs molds or yeast
- Infection of the finger vs toenail
- Extent of disease—involvement of matrix, one or two lateral edges, number of nails
- Thickness of nail plate
- Other sites of mycotic infection (palms, soles, toe webs)
- Other nail alterations affecting outcome (onycholysis, paronychia, dermatophytoma, etc.)
- Other nail diseases and symptoms
- Age and underlying medical conditions (diabetes, poor perfusion, immunocompromised)
- Drug interactions and adverse effects
- Cost of therapy

Data from References 67,69,70.

Topical Therapy

⑩Conventional topical antifungal products are available as creams, ointments, powders, and solutions. [64,7364,66,73] Mycological cure rates in open labeled trials are between 45% and 65%; however, cure rates in high quality studies are low (2%-10%). Despite this, most experts consider topical therapy a feasible option when the infection is superficial involving the nail plate without matrix involvement, such as white superficial onychomycosis, involves a partial area of the nail plate not exceeding 50% (owing to difficulty of applying treatment to the margin of the nail), is limited to a few (three or four) nails, is in the early stages of distal subungual onychomycosis when infection is still confined to the distal edge of the nail, or when systemic therapy is contraindicated.[62,66,72] Four products demonstrated cure rates between 2% and 10% after 48 weeks of treatment.[74] The highest quality of evidence was with efinconazole, an azole antifungal agent. Moderate quality evidence was with tavaborole, an oxaborole antifungal, and ciclopirox hydrolacquer. The poorest quality was with ciclopirox 8% lacquer. Amoroline 5% nail lacquer was not included in the review. In separate studies amorolfine produced higher mycologic and treatment cure rates than ciclopirox 8% lacquer.[64,72] Nail lacquers contain a volatile vehicle, used to deliver the drug, evaporates and leaves an occlusive film with a high-drug concentration on the nail surface.[66,73] These insolble therapies require nail filing before application. The ciclopirox hyprolacquer is a water soluble product that does not require nail filing for absorption into the nail.[62,66,72] Combining topical therapy with debridement of the affected nail (thus diminishing the amount of nail requiring treatment) may increase the likelihood of successful treatment, although there is no strong supporting evidence.[71] Topical therapy is not associated with systemic adverse effects or drug interactions. Any adverse effect will be localized to the application site, such as mild erythema in the adjacent skin area.

Systemic Therapy

Oral antifungal therapy is considered to be more effective than topical for treating onychomycosis. Terbinafine and itraconazole (capsule), the first-line agents for treatment, have yielded higher efficacy rates using shorter treatment periods (generally 3 months or shorter) for toenail and fingernail onychomycosis compared with the traditional agents, such as griseofulvin and ketoconazole, which are rarely used nowadays. Terbinafine, an allylamine, exerts fungicidal activity and demonstrates the greatest in vitro activity against dermatophytes compared with the other oral antifungals; it has good activity against nondermatophyte molds and only marginal activity against *Candida* species.[62,73] Like other azoles, itraconazole is fungistatic, has a broad antifungal spectrum, and is active against dermatophytes, nondermatophyte molds, and *Candida* species.[62,73] Both agents have lipophilic and keratinophilic properties, which explains their excellent penetration (appearing in the nail plate within days of treatment initiation) and accumulation in the nails, achieving concentrations far exceeding the minimal inhibitory concentration (MIC) of most dermatophytes. Nail terbinafine concentrations are detected within 1 week of starting therapy, whereas itraconazole can be detected 1 (fingernails) to 2 weeks (toenails) after starting therapy.[66] Both drugs are slowly eliminated from the nail, with effective drug concentrations persisting in nails for 30 to 36 weeks after completion of treatment with terbinafine and for 27 weeks with itraconazole.[68] The persistence of drug in the nails explains in part the long-term protection against relapses after the end of treatment and also permits use of intermittent (pulse) dosing.

The treatment of toenail onychomycosis requires a 12-week course, whereas a 6-week course is adequate for fingernail onychomycosis with either drug (see Table 143-8).[63,68,75] Terbinafine is the first-line agent for onychomycosis; itraconazole is the alternative. Terbinafine is more effective than itraconazole either by continuous or pulse dosing.[62,72,73] Mycologic cure rates for terbinafine range from 77% to 100% depending on the study.[66,76,77] Continuous terbinafine was the most effective therapy for toenail onychomycosis.[78–81] In addition, terbinafine was reported to achieve high cure rates in high-risk immunosuppressed patients, such as diabetics and organ transplant recipients, comparable to the immunocompetent population, with no significant adverse effects or drug interactions. It also appears to be effective in HIV patients and nondermatophyte infections.[75,81,82] Itraconazole pulse therapy is the preferred method over continuous dosing for fingernail infections, and it is licensed as twice-daily dosing for a 1-week cycle per month for two consecutive months (ie, two pulses), or as daily therapy for 6 weeks (see Table 143-8).[68,75] Although itraconazole pulse therapy is not approved by the US Food and Drug Administration (FDA), three or four pulses are effective for toenail infections; otherwise, half the dose is taken daily for 3 months (see Table 143-8).[68,75] In addition to lower drug cost, the potential advantages of itraconazole pulse therapy compared with continuous therapy are a lower risk of adverse drug effects and improved patient adherence.

Terbinafine was the most cost-effective therapy in terms of highest success rate, lowest relapse rate, and highest number of disease-free days for both fingernail and toenail infections.[83] The cost per cure with the use of oral terbinafine (based on cure rates from clinical trials) ranged from $2,439 to $7,944, depending on disease severity.[84] Compared with the amount of money a patient would consider reasonable to spend on treatment, the expense for a course of systemic therapy is considerably higher.[84,85]

Both terbinafine and itraconazole generally are well tolerated. The more common adverse effects reported with terbinafine are GI (eg, diarrhea, dyspepsia, nausea, and abdominal pain), dermatologic (eg, rash, urticaria, and pruritus), and headache; less common adverse effects are taste disturbances, fatigue, inability to concentrate, and asymptomatic liver enzyme abnormalities.[68,72,75] Terbinafine can cause transient decrease in absolute lymphocyte counts; hence, monitoring of complete blood counts can be useful, especially in immunocompromised patients.[75] Although uncommon, severe adverse effects have been reported with terbinafine, including erythema multiforme, Stevens-Johnson's syndrome, toxic epidermal necrolysis, pancytopenia, lupus erythematosus, psoriasis, hair loss, and hepatotoxicity. Severe hepatotoxicity is rare.[86] Terbinafine thus is not recommended for patients with chronic or active liver disease, although hepatotoxicity can occur in patients with no preexisting liver disease or serious underlying medical condition. Prior to initiating terbinafine treatment, it is recommended to obtain appropriate nail specimens for laboratory testing to confirm the diagnosis of onychomycosis. Liver function parameters (serum transaminases) should be assessed at baseline and periodically during treatment with terbinafine.[75,86]

The common adverse effects of itraconazole are similar to those of terbinafine, such as GI disturbance, dermatologic disorders, and headache; less common adverse effects include dizziness, fatigue, fever, decreased libido, and asymptomatic liver enzyme abnormalities (1%-5% with continuous dosing and ~2% with pulse dosing).[68,72,87] Although still considered rare, 24 serious cases of liver failure, including transplantation and death, have been reported with the use of itraconazole.[86] Some of these patients did not have preexisting liver disease or serious underlying medical conditions, and some developed within the first week of treatment. Itraconazole should be avoided in patients with elevated liver enzymes or active liver disease or in those who have experienced other drug-induced liver toxicity. Liver function parameters (serum transaminases) should be assessed prior to and periodically during treatment. However, some experts have suggested that frequent monitoring is not as necessary if pulse therapy is used because symptomatic hepatotoxicity has not been reported with pulse therapy.[87] In addition, there is risk of developing congestive heart failure (CHF) associated with the use of itraconazole, possibly related to its potential negative inotropic effect.[63,76] Therefore, itraconazole should not be used in patients with evidence of ventricular dysfunction, such as CHF. Symptomatic assessment for the development of CHF also should be included as part of therapy monitoring. Before a patient is subjected to several months of itraconazole treatment, it is important to confirm the diagnosis of onychomycosis.

In contrast to the azoles, terbinafine does not inhibit the cytochrome P450 (CYP)3A4 isoenzymes, but it is a potent inhibitor of the CYP2D6 isoenzymes, which are responsible for metabolism of tricyclic antidepressants and other psychotropic drugs.[63,68,75] The most significant drug interactions with terbinafine are decreased clearance of 33% by cimetidine and increased clearance of 100% by rifampin. Other drug interactions of variable clinical significance are tricyclic antidepressants, cyclosporine, caffeine, theophylline, and terfenadine. Itraconazole and its major metabolite can inhibit the

CYP3A4 isoenzymes and result in numerous clinically significant drug interactions where coadministration with several drugs are contraindicated (eg, alprazolam, midazolam, triazolam, pimozide, lovastatin, simvastatin, cisapride, and terfenadine).[62,68,75]

Fluconazole is also active against dermatophytes, *Candida* species, and some nondermatophytes;[68,72] however, it does not have FDA approval for treatment of onychomycosis. The overall mycologic cure rate of fluconazole is 48%, which is lowest compared with all other oral agents.[78] The most effective dose and treatment duration have not been clearly established, with a variety of dosing regimens used, ranging from 50 mg daily to 300 mg once weekly for 6 to 12 months (see Table 143-8).[68,75] The advantages of fluconazole include a relatively good safety profile and fewer drug interactions compared with itraconazole.[68,75]

These three oral antifungal agents have superseded the use of griseofulvin and ketoconazole as treatments of choice for onychomycosis.[62,72,73] Griseofulvin has a narrow antifungal spectrum, low clinical efficacy, especially for toenail infections, high relapse rates, and the need for prolonged treatment duration (up to 12-18 months for toenails). Use of ketoconazole is also associated with high relapse rates, and the prolonged treatment duration carries an increased risk of hepatotoxicity.

Treatment Response and Recurrence

Treatment failures and recurrence rates of infection following initial cure are high, ranging from 20% to 50%.[63,71] Recurrence could be either a relapse (original infection not completely cured) or reinfection (new infection after achieving a cure of the original). Factors associated with poor response to systemic therapy include a compromised immune system (AIDS), reduced blood flow (diabetes, peripheral vascular disease, vasculitis, connective tissue disease, and CHF), coexisting nail disease (psoriasis), nail factors (slow growth, thick nails, and severe disease), drug-resistant organisms because of extensive prior drug exposure, and reduced bioavailability (absorption problems, poor compliance, and drug interactions).[68,71] To improve treatment outcomes and reduce recurrence, patients should be counseled on the importance of proper foot hygiene, for example, wearing breathable footwear and 100% cotton socks with frequent changes, keeping the nails short and clean, keeping the feet dry, protecting the feet in shared bathing areas, treating tinea pedis, and controlling other predisposing medical conditions.[71]

The use of combination therapy (topical–oral or oral–oral agents) can improve cure rates and shorten treatment duration, as this approach provides complementary mechanisms of attack.[71,72] Favorable results were achieved with itraconazole or terbinafine combined with amorolfine.[71,72] To date, no specific combination has been approved or endorsed for use. Other novel approaches include giving supplemental therapy and use of boosted therapy.[71,72] The efficacy and role of either approach remain to be defined.

ABBREVIATIONS

SELF-ASSESSMENT QUESTIONS

1. The goal of therapy in patients with VVC is:

   A. Resolution of symptoms

   B. Eradication of viable *Candida*

   C. A test of cure

   D. No recurrence within 6 weeks of therapy

2. The following should be recommended as a general approach to treatment of VVC:

   A. Keep vagina clean by douching

   B. Soothe skin with warm baths

   C. Avoid harsh soaps

   D. All the above

3. A young otherwise healthy female is determined to have VVC. She had the same symptoms 2 years ago. Which of the following would be the best treatment for her?

   A. Fluconazole 150 mg tablet, 1 orally × 3 day

   B. Miconazole 200 mg suppository, 1 per vagina × 3 days

C. Clotrimazole 100 mg tablet, 1 per vagina × 3 days

D. Nystatin 100,000 unit tablet, 1 orally × 14 days

4. A 33-year-old pregnant female has the classic symptoms of VVC. Which of the following would be the best treatment option for her?

   A. Tiaconazole 6.5% cream, 1 applicator per vagina × 4 days

   B. Fluconazole 150 mg, 1 orally × 7 days

   C. Nystatin 100,000 unit tablet, 1 tablet orally × 14 days

   D. Clotrimazole 100mg tablet, 1 per vagina × 7 days

5. A young patient with diabetes who has had four episodes of VVC in the last 8 months has tested positive for *C. glabrata*. Which of the following treatments should be used for induction therapy?

   A. Boric acid suppositories 600 mg × 14 days

   B. Fluconazole 150 mg tablet × 10 days

   C. 5 Flucytosine cream 1000 mg × 14 days

   D. Itraconazole 100 mg tablet × 10 days plus oral lactobacillus

6. OPC is an opportunistic infection that is common in which of the following clinical settings?

   A. HIV patients on effective ART

   B. Patients receiving short course antimicrobial therapy

   C. Patients with hematological and other malignancies

   D. Adults with poor dental hygiene

7. Which of the following products would be best for patients who have a mild form of OPC but also complain of xerostomia and diabetes mellitus?

   A. Nystatin suspension

   B. Clotrimazole troche

   C. Amphotericin B suspension

   D. Miconazole mucoadhesive tablets

8. The best option for the treatment of a HIV-infected patient with esophageal candidiasis would be which of the following options?

   A. Clotrimazole troches

   B. Fluconazole oral tablets

   C. Itraconazole oral suspension

   D. Nystatin oral suspension

9. A patient with profound neutropenia due to chemotherapy for acute leukemia has developed severe esophageal candidiasis. Which of the following is the best recommendation to treat this infection?

  A. Amphotericin b IV
  B. Fluconazole IV
  C. Itraconazole IV
  D. Micafungin IV

10. Which of the following is the best strategy to prevent future episodes of mucosal candidiasis in HIV-infected patients?
    A. Primary prophylaxis
    B. Secondary prophylaxis
    C. Long-term suppressive therapy
    D. Appropriate antiretroviral therapy
11. Risk factors for refractory oral mucosal candidiasis include which of the following:
    A. Prolonged antibiotic exposure, uncontrolled HIV-infection, prior use of an azole antifungal
    B. Uncontrolled HIV-infection, repeated courses of antifungal therapy, poor adherence to antifungal therapy
    C. Prolonged antibiotic exposure, colonization with non–*C. albicans* species, prior azole therapy
    D. Colonization with non–*C. albicans* species, poor adherence to antifungal therapy
12. A young female was recently diagnosed with HIV infection through routine pregnancy screening. She is currently asymptomatic and has started on antiretroviral therapy.
    A. She should be started on primary antifungal prophylaxis with fluconazole.
    B. Antifungal prophylaxis should be offered but is not required unless symptomatic.
    C. Antifungal prophylaxis should be reserved until after her first episode of oral mucosal candidiasis.
    D. Neither primary nor secondary antifungal prophylaxis should be considered in this patient.
13. When is oral therapy recommended in patients with tinea pedis?
    A. Mild infections
    B. Moccasin-type
    C. Involvement of the nail
    D. Presentation with vesicles and pustules
14. A 76-year-old male patient with CHF and diabetes has just been diagnosed with onychomycosis in his fingers. Which of the following would be considered the most effective therapy?
    A. Terbinafine × 6 weeks
    B. Terbinafine × 12 weeks
    C. Itraconazole pulse × 3 months

D. Ciclopriox × 48 weeks

15. Which of the following is not a strategy to prevent the recurrence of onychomycosis?

   A. Protect feet in shared bathing areas

   B. Keep feet dry

   C. Manicure with nail polish

   D. Wear cotton socks

SELF-ASSESSMENT QUESTION-ANSWERS

1. **A.** Asymptomatic colonization does not need to be treated.

2. **C.** Warm baths and douching can cause further irritation.

3. **B.** Nystatin is inferior to the azoles, and doses for the azoles other than clotrimazole are incorrect.

4. **D.** Oral therapy should not be used due to the risk of fetal abnormalities. Nystatin and courses of therapy less than 7 days are inferior.

5. **A.** The dose of 5 flucytosine is incorrect and azoles are inferior.

6. **A.** Such patient populations are those with impaired immune systems due to diseases, such as malignancy or diabetes, infection with HIV, and extremes of age (neonates, very elderly). Other significant risk factor is prolonged exposure to broad-spectrum antibiotics.

7. **D.** In patients with diabetes miconazole tablets have the advantage of less sucrose content.

8. **A.** Nystatin and clotrimazole are not suitable for esophageal candidiasis. Fluconazole is superior to ketoconazole and itraconazole tablets and comparable to itraconazole suspension with fewer drug interactions.

9. **C.** Echinocandin or amphotericin B preferred in severe disease or patients at high risk of dissemination of infection. Echinocandins generally preferred over amphotericin B in patients at high risk of nephrotoxicity due to other drugs.

10. **D.** Antifungal therapy for OPC in patients with inadequately controlled HIV infection will only give a transient clinical response and high risk of relapse. Treatment with effective antiretroviral therapy is critical for these patients.

11. **B.** Refer to the Section “Antifungal-Refractory Oral Mucosal Candidiasis” for risk factors for refractory and recurrent oral mucosal candidasis.

12. **D.** Currently neither primary nor secondary antifungal prophylaxis is recommended for OPC due to availability of effective therapy, low risk of serious invasive disease, and high incidence of adverse effects or drug interactions with antifungal therapy.

13. **C.** Refer to the Section “Tinea Pedis.” Most forms of Tinea Pedis can be treated with topical agents; however, infection of the nail requires oral therapy.

14. **A.** Refer to Table 98-8 and to the Section “Systemic Therapy.” Oral therapy is still considered more effective than topical for treatment of onychomycosis. Treatment of finger infections are shorter duration compared to regimens for toenail onychomycosis.

15. **C.** To improve treatment outcomes and prevent recurrence appropriate foot hygiene should be emphasized.

Chapter 144: Invasive Fungal Infections

Peggy L. Carver; Gregory A. Eschenauer

KEY CONCEPTS

KEY CONCEPTS

① Systemic mycoses can be caused by pathogenic fungi and include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, or infections by opportunistic fungi such as *Candida albicans*, *Aspergillus* species, *Trichosporon*, *Candida glabrata*, *Fusarium*, *Alternaria*, and *Mucor*.

② The diagnosis of fungal infection is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. Rapid, accurate diagnostic laboratory tests are currently under development.

③ Histoplasmosis is caused by *Histoplasma capsulatum* and is endemic in parts of the central United States along the Ohio and Mississippi River valleys, and in Central and South America. Although most patients experience asymptomatic infection, some can experience chronic, disseminated disease.

④ Asymptomatic patients with histoplasmosis are not treated, while patients with evident disease are treated with either oral itraconazole or an IV amphotericin B lipid formulation.

⑤ Blastomycosis is caused by *Blastomyces dermatitidis*. In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All persons with moderate-to-severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.

⑥ Coccidioidomycosis is caused by *Coccidioides immitis* and *Coccidioides posadasii and* is endemic in some parts of the southwestern United States. It can cause nonspecific symptoms, acute pneumonia, or chronic pulmonary or disseminated disease. Primary pulmonary disease (unless severe) frequently is not treated, whereas disseminated and meningeal disease is treated with fluconazole.

⑦ Cryptococcosis is caused by *Cryptococcus neoformans*, which occurs primarily in immunocompromised patients, and *Cryptococcus gattii*, which occurs primarily in nonimmunocompromised patients. Patients with acute meningitis are treated with lipid formulations of amphotericin B with flucytosine. Patients infected with human immunodeficiency virus (HIV) often require long- term suppressive therapy with fluconazole or itraconazole.

⑧ A variety of *Candida* species (including *C. albicans*, *C. glabrata*, *Candida tropicalis*, *Candida parapsilosis*, and *Candida krusei*) can cause diseases such as mucocutaneous, oral, esophageal, vaginal, and hematogenous candidiasis, as well as candiduria. Candidemia can be treated with a variety of antifungal agents; the optimal choice depends on previous patient exposure to antifungal agents, potential drug interactions and toxicities of each agent, and local epidemiology of intensive care unit (ICU) or hematology–oncology centers.

⑨ Aspergillosis can be caused by a variety of *Aspergillus* species that can cause superficial infections, pneumonia, allergic bronchopulmonary aspergillosis (BPA), or invasive infection. Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with invasive aspergillosis (IA). Combination therapy may be considered in cases of severe infection, especially in patients with persistent neutropenia.

INTRODUCTION

①Advances in medical technology including organ and bone marrow transplantation, cytotoxic chemotherapy, the widespread use of indwelling IV catheters, and the increased use of potent broad- spectrum antimicrobial agents all have contributed to the dramatic increase in the incidence of fungal infections worldwide.[1–3] Problems remain in the diagnosis, prevention, and treatment of fungal infections.[1,4–6] The Infectious Diseases Society of America (IDSA) publishes guidelines regarding the prophylaxis and treatment of many commonly encountered fungal infections.[7–12]

MYCOLOGY

Fungi are eukaryotic organisms with a defined nucleus enclosed by a nuclear membrane; a cytoplasmic membrane containing lipids, glycoproteins, and sterols, mitochondria, golgi apparatus, and ribosomes bound to endoplasmic reticulum; and a cytoskeleton with microtubules, microfilaments, and intermediate filaments. Fungi have rigid cell walls composed of chitin, cellulose, or both that stain with Gomori methenamine silver or periodic acid–Schiff reagent. Most fungi, except *Candida* species, are too weakly gram-positive to be seen well on Gram stain. *Cryptococcus neoformans* has a polysaccharide capsule surrounding the cell wall.[1]

Morphologically, pathogenic fungi can be grouped as either filamentous molds or unicellular yeasts (Fig. 144-1). *Molds* grow as multicellular branching, threadlike filaments (hyphae) that are either septate (divided by transverse walls) or coenocytic (multinucleate without crosswalls). Yeasts are oval or spherically shaped unicellular forms that generally produce pasty or mucoid colonies on agar medium similar to those observed with bacterial cultures. Yeasts have rigid cell walls and reproduce by budding, a process in which daughter cells arise from pinching off a portion of the parent cell.

Many pathogenic fungi, including the etiological agents of histoplasmosis, coccidioidomycosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis, are termed *dimorphic fungi*. These pathogens can exist as either a yeast or a mold, depending on the pathogen, ambient CO_2, the production of host 17-beta-estradiol, the site of growth (in the host or in the laboratory setting), and temperature. Temperature shifts provoke reversible conversions between the hyphal (22-25^{o}C) and yeast (37^{o}C) phases. Dimorphic fungi can infect humans with either normal or impaired host immune defenses. Usually, yeasts are the parasitic form that invades human or animal host tissue, whereas molds are the free-living form found in the environment.[13]

Clinical Versus Microbial Resistance

Host factors contribute greatly to clinical outcome. A patient may respond clinically to treatment with an antifungal agent despite resistance to that agent in vitro because the patient's own immune system may eradicate the infection, or the agent may reach the site of infection in high concentrations. Thus, in vitro susceptibility does *not* necessarily equate with in vivo clinical success, and in vitro resistance might *not* always correlate with treatment failure.[6]

It is important to distinguish between clinical resistance and microbial resistance. *Clinical resistance* refers to failure of an antifungal agent in the treatment of a fungal infection that arises from factors other than microbial resistance, such as failure of the antifungal agent to reach the site of infection or inability of a patient's immune system to eradicate a fungus whose growth is retarded by an antifungal agent.[14]

Microbial resistance can refer to *primary* or *secondary* resistance, as determined by in vitro susceptibility testing using standardized methodology. *Primary* or *intrinsic resistance* refers to resistance recorded prior to drug exposure in vitro or in vivo. *Secondary* or *acquired resistance* develops on exposure to an antifungal agent and can be either reversible, owing to transient adaptation, or acquired as a result of one or more genetic alterations.[14] It is possible for a patient to respond clinically to treatment with an antifungal agent, despite resistance to that agent in vitro, because the patient's own immune system may eradicate the infection, or the agent reaches the site of infection in high concentrations.[6]

Susceptibility Testing of Antifungal Agents

Most laboratories do not routinely perform susceptibility tests on fungal isolates, but standardized methods for performing these tests are being developed and are now available for testing selected yeasts. As the prevalence of nosocomial and community-acquired fungal infections become more prominent, the need for in vitro susceptibility testing increases. Susceptibility testing is occasionally indicated, for example, in a patient with prolonged fungemia with a presumed susceptible isolate, and is most helpful in dealing with infections caused by non-*albicans* species of *Candida*.[5–7]

Clinical breakpoints (CBPs) are antimicrobial concentrations (MICs) obtained from susceptibility testing, which are used to define isolates as susceptible, intermediate, or resistant. No CBPs have been established for posaconazole, isavuconazole, or amphotericin B versus *Candida*, or for antifungal agents and filamentous fungi such as *Aspergillus*.[6] CBPs can be used to differentiate strains for which there is a high likelihood of treatment success (organisms that are clinically susceptible [S]), from those for which treatment is more likely to fail (clinically resistant [R]) (Tables 144-1–144-3). A clinically intermediate (I) or susceptible dose-dependent (SDD) category can be assigned to pathogens for which the level of antimicrobial agent activity is associated with uncertain therapeutic effect, implying that infections due to the isolate may be appropriately treated in body sites where the drugs are physically concentrated or when a high dosage of drug can be used. Although CBPs are designed to guide therapy, they do not distinguish between fungal isolates with or without resistance mechanisms, nor do they always allow for early detection of resistant isolates.[6] Table 144-3 shows the currently approved interpretive CBPs for *Candida* species.

TABLE 144-1

General Patterns of In Vitro Susceptibility of *Candida* Species

Patterns of Susceptibility							
	Azoles					Echinocandins	Amphotericin B
***Candida* species**	**Fluconazole**	**Itraconazole**	**Voriconazole**	**Posaconazole**	**Isavuconazole**	**Caspofungin** **Anidulafungin** **Micafungin**	
C. albicans	Yes	Yes	Yes	Yes	Yes	Yes	Yes
C. tropicalis	Yes	Yes	Yes	Yes	Yes	Yes	Yes
C. parapsilosis	Yes	Yes	Yes	Yes	Yes	Yes[a]	Yes
C. glabrata	Variable[b]	Variable[b]	Variable[b]	Variable[b]	Variable[b]	Yes	Yes
C. krusei	No	Yes	Yes	Yes	Yes	Yes	Yes
C. lusitaniae	Yes	Yes	Yes	Yes	Yes	Yes	Variable[c]

[a] Most isolates of *C. parapsilosis* have reduced susceptibility to echinocandins.

[b] Approximately 15% of *C. glabrata* isolates are resistant to fluconazole; *C. glabrata* generally exhibits cross-resistance across the azole class.[15]

[c] Although frank resistance to amphotericin B is not observed in all isolates, it is well described for isolates of *C. lusitaniae*.

	C. glabrata	---	---	---	---
	C. krusei	≤0.5	1	---	≥2
	C. parapsilosis	≤0.12	0.25-0.5	---	≥1
	C. tropicalis	≤0.12	0.25-0.5	---	≥1

[a] Clinical Breakpoints have not been established for isavuconazole by CLSI.

S, susceptible; I, intermediate; SDD, susceptible-dose dependent; R, resistant; ---, not defined or not applicable

Data from Reference 6.

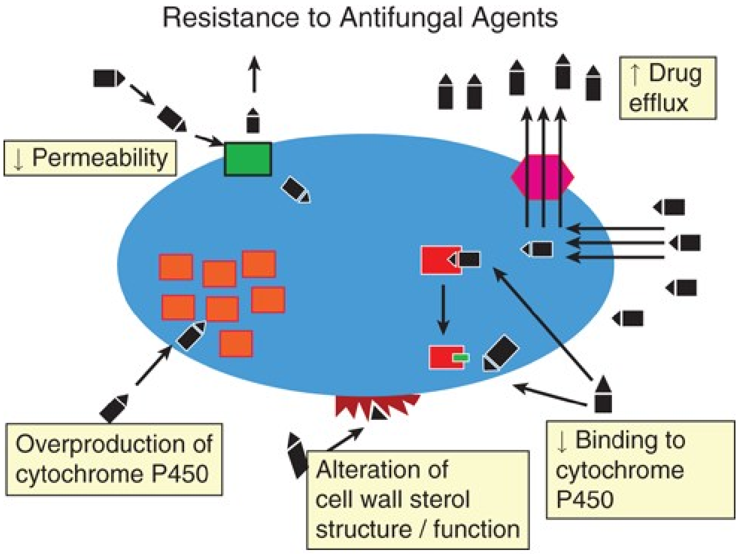
Resistance to Antifungal Agents

Understanding mechanisms of resistance is an important process in the optimization of antifungal therapy. The most exhaustive and definitive accounts of antifungal resistance have been described in *Candida* species, in particular *C. albicans* and, to a lesser extent, *C. glabrata*, *C. tropicalis*, and *Candida krusei*, as well as in a few *C. neoformans* isolates.[14] *C. glabrata* isolates are increasingly resistant to both azole and echinocandin antifungal agents.

There are four different mechanisms that result in azole resistance: (a) mutations or upregulation of *ERG11* (an enzyme involved in the ergosterol biosynthesis pathway), (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins (Fig. 144-2). Although detailed analysis of each of the elucidated mechanism of resistance is beyond the scope of this chapter, interested readers are referred to a publication that has comprehensively summarized this topic.[14]

FIGURE 144-2

Mechanisms of azole resistance. Four different mechanisms result in azole resistance: (a) mutations or upregulation of *ERG11*, the target enzyme of azoles, (b) expression of multidrug efflux transport pumps that decrease antifungal drug accumulation within the fungal cell, (c) alteration of the structure or concentration of antifungal drug target proteins, and (d) alteration of membrane sterol proteins.



Resistance to Antifungal Agents
↑ Drug efflux
↓ Permeability
Overproduction of cytochrome P450
Alteration of cell wall sterol structure / function
↓ Binding to cytochrome P450

Source: Joseph T. DiPiro, Gary C. Yee, L. Michael Posey, Stuart T. Haines, Thomas D. Nolin, Vicki L. Ellingrod: *DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e*
Copyright © McGraw Hill. All rights reserved.

The most commonly reported mechanisms of azole resistance among *C. albicans* isolates include reduced permeability of the fungal cell membrane to azoles, modification or overproduction of the target fungal enzymes (cytochrome P450, CYP) resulting in decreased binding of the azole to the target site, alterations in sterol synthesis, and activation of efflux pumps capable of actively pumping azoles from the target pathogen. Fluconazole resistance is observed most frequently in *C. glabrata*, which is often resistant, and in *C. krusei*, for which fluconazole resistance is universal.[5,14] With the increase in echinocandin use, there has been an increase in the number of reports of echinocandin-resistant isolates from patients failing therapy. Echinocandin exposure and previous episodes of *C. glabrata* are predictors of FKS gene mutations in *Candida*.[17,18]

Although, to date, the rate of amphotericin B resistance remains low, the exact incidence remains difficult to quantify and the response to antifungal agents difficult to characterize.[6] As such, no consensus for therapy has been formulated at this time, although clinicians should keep in mind that *C. glabrata, Candida guilliermondii, C. krusei*, and *Candida lusitaniae* may have a higher propensity to developing resistance than other species.

Acquired resistance of *Aspergillus* species during long-term azole exposure, while still relatively uncommon, is emerging, and varies widely between geographic centers. Acquisition of primary-resistant isolates is also increasing, due to the agricultural use of azoles.[19] Cross-resistance of azole-resistant strains of *Aspergillus* to amphotericin B has not been described. Azole resistance among *Aspergillus* spp. (specifically *Aspergillus fumigatus*) is predominantly mediated by specific point mutations in TR/L98H in the CYP51A gene promoter region, causing amino acid changes and tandem repeats, and often results in cross-resistance with azole antifungals.[19]

EPIDEMIOLOGY AND PATHOGENESIS

Systemic mycoses caused by primary or pathogenic fungi include histoplasmosis, coccidioidomycosis, cryptococcosis, blastomycosis, paracoccidioidomycosis, and sporotrichosis. Primary pathogens can cause disease in both healthy and immunocompromised individuals, although disease generally is more severe or disseminated in the immunocompromised host.[1] *Candida* species are commensals in humans, and most infections are iatrogenic.[20] Mycoses caused by opportunistic fungi such as *Aspergillus* species, *Fusarium*, *Alternaria*, and *Mucor* are found only in the immunocompromised host.[1]

Most fungal infections are acquired as a result of accidental inhalation of airborne conidia. For example, *Histoplasma capsulatum* is found in soil contaminated by bat, chicken, or starling excreta, and *C. neoformans* is associated with pigeon droppings. Although some fungi, including *C. neoformans*, and *Aspergillus* species, are ubiquitous pathogens with worldwide distribution, other fungi have regional distributions associated with specific geographic environments.[1]

Invasive fungal infections (IFIs) are a major cause of morbidity and mortality in the immunocompromised patient.[21,22] Patients with decreased neutrophil counts or decreased neutrophil function are at higher risk of infections, particularly infections caused by *Candida* and *Aspergillus* species. In patients with hematologic malignancies and following hematopoietic stem cell transplantation (HSCT), there has been a shift in the most commonly encountered IFIs from *Candida* spp. to *Aspergillus* spp.[23,24]

Nosocomially acquired fungal infections can arise from either exogenous or endogenous flora. Endogenous flora can include normal commensal organisms of the skin, GI, genitourinary, or respiratory tract. *C. albicans* is found as a normal commensal of the GI tract in 20% to 30% of humans. A complex interplay of host and pathogen factors influences the acquisition and development of fungal infections. Intact skin or mucosal surfaces serve as primary barriers to infection. Alterations in the balance of normal flora caused by the use of antibiotics or alterations in nutritional status can allow the proliferation of fungi such as *Candida*, increasing the likelihood of systemic invasion and infection.[20] *Candida* species are the fourth most commonly isolated bloodstream isolate.[25]

Diagnosis and Rapid Diagnostic Tests

② The diagnosis of IFIs is accomplished by careful evaluation of clinical symptoms, results of serologic tests, and histopathologic examination and culture of clinical specimens. While direct microscopy, culture and histological techniques constitute the “gold standard” for diagnosis, obtaining biopsies from sterile body sites for these studies is a highly invasive approach that may not be possible in severely ill patients. Also, histopathology lacks sensitivity and selectivity, as several filamentous fungi may exhibit undistinguishable morphologies. Further, the finding of a positive culture from a sterile site may indicate transient colonization and not true infection, especially for opportunistic fungi. Fungi may require special laboratory conditions, with additional time (up to 4 days) required in order to obtain species identification and the results of susceptibility testing. Some species, such as *C. glabrata*, tend to grow more slowly; initial identification of yeast from blood averages 100 hours (~4 days) in most institutions.[27] Several rapid, accurate diagnostic laboratory tests, including matrix-assisted laser desorption ionization time-of-flight mass spectrometry (MALDI-TOF), peptide nucleic acid (PNA) in situ hybridization (PNA-FISH), PCR, galactomannan, and T2 magnetic resonance assays, have the potential to enhance sensitivity and speed of diagnosis of IFIs.[28,29]

New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other molds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. These underscore the need for rapid diagnosis and identification of clinically significant isolates to species level, and the need for susceptibility testing.[28]

Risk Factors for Fungal Infections

Increasing use of aggressive and intensive cancer chemotherapeutic regimens, immunosuppressive therapy for autoimmune disorders, and transplantation have led to an increase in the number of susceptible hosts, contributing to the changing epidemiology of fungal infections. Infection epidemiology can drastically vary depending on patients’ underlying concomitant conditions, comorbidities, confounding risk factors, and geographical area.[20]

A clinical indicator for a patient’s immunologic status is the quantitation of absolute neutrophil count (ANC). Neutropenia, defined as an ANC ≤ $500/mm^3$ (0.5×10^9/L), dramatically escalates the risk of acquiring and opportunistic infection. Major risk factors for *Candida* bloodstream infections (BSIs) in ICU patients include the use of central venous catheters (CVCs), receipt of multiple antibiotics or parenteral nutrition (PN), extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization.[26]

TREATMENT

Invasive Mycoses

Strategies for the prevention or treatment of invasive mycoses can be classified broadly as prophylaxis, early empirical therapy, empirical therapy, and secondary prophylaxis or suppression. In patients undergoing cytotoxic chemotherapy, antifungal therapy is directed primarily at the prevention or treatment of infections caused by *Candida* and *Aspergillus* species.

Prophylactic therapy with oral or IV antifungal agents is administered prior to and throughout periods of granulocytopenia (absolute neutrophil count

< 1,000 cells/μL [1 × 10^9/L]) or other immunosuppressive events (such as development of graft-versus-host disease (GvHD) in hematopoietic stem cell transplant recipients). The potential benefits of prophylactic therapy must be weighed against the potential risks inherent in each regimen, including safety, efficacy, cost, the prevalence of infection, and the potential consequences (eg, resistance) of widespread use.[23,24]

Empirical therapy is the administration of systemic antifungal agents in patients with signs and symptoms of fungal infection, but without confirmation of infection. For example, empirical therapy with systemic antifungal agents is administered to granulocytopenic patients with persistent or recurrent fever despite the administration of appropriate antimicrobial therapy.[30,31]

Secondary prophylaxis (or *suppressive therapy*) is the administration of systemic antifungal agents (generally prior to and throughout the period of granulocytopenia) to prevent relapse of documented IFI.[32]

HISTOPLASMOSIS

In humans, histoplasmosis is caused by inhalation of dust-borne microconidia of the dimorphic fungus *H. capsulatum*. Although there exist two dimorphic varieties of *H. capsulatum*, the small-celled (2-5 μm) form (var. *capsulatum*) occurs globally, whereas the large-celled (8-15 μm) form (var. *duboisii*) is confined to the African continent and Madagascar. In tissues stained by conventional techniques, *H. capsulatum* appears as an oval or round, narrow-pore, budding, unencapsulated yeast.[33]

Epidemiology

③Although histoplasmosis is found worldwide, certain areas of North, Central, and South America are recognized as highly endemic areas. In the United States, most disease is localized along the Ohio and Mississippi River valleys, where more than 90% of residents may be affected. However, due to differences in reporting requirements, variable diagnostic methodologies and capabilities, and a lack of adequate surveillance, particularly in low-resource settings, infections occur in other areas. Infections have been increasingly identified in some classically “non-endemic” areas of the United States, including the Rocky Mountain states (Montana and Idaho), the southeast (Florida and South Carolina), and the North Central states of Minnesota and North Dakota. Additional cases are being reported in Africa, Asia, and worldwide, in patients with HIV or those receiving immunosuppressive agents.[34]

Precise reasons for this endemic distribution pattern are unknown but are thought to include moderate climate, humidity, and soil characteristics. *H. capsulatum* is found in nitrogen-enriched soils, particularly those heavily contaminated by avian or bat guano, which accelerates sporulation. Blackbird or pigeon roosts, chicken coops, and sites frequented by bats, such as caves, attics, or old buildings, serve as “microfoci” of infections; once contaminated, soils yield *Histoplasma* for many years. Although birds are not infected because of their high body temperature, bats (mammals) may be infected and can pass yeast forms in their feces, allowing the spread of *H. capsulatum* to new habitats. Air currents carry the spores for great distances, exposing individuals who were unaware of contact with the contaminated site.[33]

Pathophysiology

At ambient temperatures, *H. capsulatum* grows as a mold. The mycelial phase consists of septate branching hyphae with terminal micro- and macroconidia that range in size from 2 to 14 μm in diameter. When soil is disturbed, these conidia become aerosolized and reach the bronchioles or alveoli.[33]

Animal studies demonstrate that within 2 to 3 days after reaching lung tissue, the conidia germinate, releasing yeast forms that begin multiplying by binary fission. During the next 9 to 15 days, organisms are ingested but not destroyed by large numbers of macrophages that are recruited to the infected site, resulting in small infiltrates. Infected macrophages migrate to the mediastinal lymph nodes and other sites within the mononuclear phagocyte system, particularly the spleen and liver. At this time, the onset of specific T-cell immunity in the nonimmune host activates the macrophages, rendering them capable of fungicidal activity. Tissue granulomas form, many of which develop central caseation and necrosis over the next 2 to 4 months. Over a period of several years, these foci become encapsulated and calcified, often with viable yeast trapped within the necrotic tissue.[33]

Cellular immunity, as measured by histoplasmin skin-test reactivity, wanes in the absence of occasional reexposure. Although exposure to heavy inocula can overcome these immune mechanisms, resulting in severe disease, reinfection occurs frequently in endemic areas. In the immune individual, the reactions of acquired immunity begin 24 to 48 hours after the appearance of yeast forms, resulting in milder forms of illness and little proliferation of organisms. Although viable organisms can be found within granulomas years after initial infection, the organisms appear to have little ability to proliferate within the fibrous capsules, except in immunocompromised patients.[33]

Clinical Presentation

The outcome of infection with *H. capsulatum* depends on a complex interplay of host, pathogen, and environmental factors.[10,33] Host factors include the degree of immunosuppression and the presence of immunity (from prior infection). Environmental factors include inoculum size, exposure within an enclosed area, and duration of exposure. Hematogenous dissemination from the lungs to other tissues probably occurs in all infected individuals during the first 2 weeks of infection before specific immunity has developed but is nonprogressive in most cases, which leads to the development of calcified granulomas of the liver and/or spleen. Progressive pulmonary infection is common in patients with underlying centrilobular emphysema.

Acute and chronic manifestations of histoplasmosis appear to result from unusual inflammatory or fibrotic responses to the pathogen, including pericarditis and rheumatologic syndromes during the first year after exposure, with chronic mediastinal inflammation or fibrosis, broncholithiasis, and enlarging parenchymal granulomas later in the course of disease.

In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in mild or asymptomatic pulmonary histoplasmosis. However, in Africa, infection with *H. capsulatum* var. *duboisii* results primarily in skin and soft tissue infection and only rarely in pulmonary disease.[34] The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Patients exposed to a higher inoculum during an acute primary infection or reinfection can experience an acute, self-limited illness with flu-like pulmonary symptoms, including fever, chills, headache, myalgia, and a nonproductive cough. Patients with diffuse pulmonary histoplasmosis can have diffused radiographic involvement, become hypoxic, and require ventilatory support. A low percentage of patients present with arthritis, erythema nodosum, pericarditis, or mediastinal granuloma.

Chronic pulmonary histoplasmosis generally presents as an opportunistic infection imposed on a preexisting structural abnormality, such as lesions resulting from emphysema. Patients demonstrate chronic pulmonary symptoms and apical lung lesions that progress with inflammation, calcified granulomas, and fibrosis. Patients with early, non-cavitary disease often recover without treatment. Progression of disease over a period of years, seen in 25% to 30% of patients, is associated with cavitation, bronchopleural fistulas, extension to the other lung, pulmonary insufficiency, and often death.

In patients exposed to a large inoculum and in immunocompromised hosts, successful containment of the organism within macrophages may not occur, resulting in a progressive illness characterized by yeast-filled phagocytic cells and an inability to produce granulomas. This disease, termed *disseminated histoplasmosis*, is characterized by persistent parasitization of macrophages. The clinical severity of the diverse forms of disseminated histoplasmosis (Table 144-4) generally parallels the degree of macrophage parasitization observed.

TABLE 144-4

Clinical Manifestations and Therapy of Histoplasmosis

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Acute pulmonary histoplasmosis	
Asymptomatic or mild-to-moderate disease	*Asymptomatic, mild, or symptoms <4 weeks:* No therapy is generally required. Itraconazole (200 mg three times daily for 3 days and then 200 mg once or twice daily for 6-12 weeks) is recommended for patients who continue to have symptoms for greater than 1 month[a]
Moderately severe to severe diffuse pulmonary disease	Lipid amphotericin B 3-5 mg/kg/day IV for 1-2 weeks followed by itraconazole 200 mg twice daily for 3 days then three times daily for a total of 12 weeks of therapy; methylprednisolone (0.5-1 mg/kg daily IV) during the first 1-2 weeks of antifungal therapy is recommended for patients who develop respiratory complications, including hypoxemia or significant respiratory distress
CNS histoplasmosis	Amphotericin B should be used as initial therapy (lipid formulations at 5 mg/kg/day IV, for a total dosage of 175 mg/kg for 4-6 weeks, followed by itraconazole 200 mg two or three times daily for at least a year; some patients may require lifelong therapy; response to therapy should be monitored by repeat lumbar punctures to assess *Histoplasma* antigen levels, WBC, and CSF antibody titers
Progressive histoplasmosis	*Moderately severe to severe:* Liposomal amphotericin B (3 mg/kg daily) IV, amphotericin B lipid complex (ABLC, 5 mg/kg daily) IV, or deoxycholate amphotericin B (0.7-1 mg/kg daily) for 1-2 weeks IV, followed by itraconazole (200 mg twice daily for at least 12 months) *Mild to moderate:* Itraconazole (200 mg orally twice daily for at least 12 months). Immunosuppressed patients may require lifelong suppressive therapy with itraconazole 200 mg daily

[a] Itraconazole plasma concentrations should be measured during the second week of therapy to ensure that detectable concentrations have been achieved. If the concentration is below 1 mcg/mL (mg/L; 1.4 μmol/L), the dose may be insufficient or drug interactions can be impairing absorption or accelerating metabolism, requiring a change in dosage. If plasma concentrations are greater than 10 mcg/mL (mg/L; 14 μmol/L), the dosage can be reduced.

Data from References 10,33.

Acute (infantile) disseminated histoplasmosis is characterized by massive involvement of the mononuclear phagocyte system by yeast-engorged macrophages. Typically, this severe type of infection is seen in infants and young children and (rarely) in adults with Hodgkin's disease or other lymphoproliferative disorders. In infants or children, acute disseminated histoplasmosis is characterized by unrelenting fever, anemia, leukopenia or thrombocytopenia, enlargement of the liver, spleen, and visceral lymph nodes, and GI symptoms, particularly nausea, vomiting, and diarrhea. The chest roentgenogram often demonstrates remnants of the initiating acute pulmonary lesion. Untreated disease is uniformly fatal in 1 to 2 months. A less severe "subacute" form of the disease, which occurs in both infants and immunocompetent adults, is characterized by focal destructive lesions in various organs, weight loss, weakness, fever, and malaise. Untreated disease is fatal in approximately 10 months.

Most adults with disseminated histoplasmosis demonstrate a mild, chronic form of the disease. Untreated patients often are ill for 10 to 20 years, demonstrating long asymptomatic periods interrupted by relapses of clinical illness characterized primarily by weight loss, weakness, and fatigue. Chronic disseminated histoplasmosis can be seen in patients with lymphoreticular neoplasms (Hodgkin's disease) and patients undergoing immunosuppressant chemotherapy for organ transplantation or for rheumatic diseases. Although CNS involvement occurs in 10% to 20% of patients with severe underlying immunosuppressive conditions, focal organ involvement is uncommon. The disease is characterized by the development of focal granulomatous lesions, often with bone marrow involvement resulting in thrombocytopenia, anemia, and leukemia. Fever, hepatosplenomegaly, and GI ulceration are common.

Histoplasmosis in HIV-Infected Patients

Adult patients with AIDS demonstrate an acute form of disseminated disease that resembles the syndrome seen in infants and children. Progressive disseminated histoplasmosis (PDH), which is defined as a clinical illness that does not improve after at least 3 weeks of observation and that is associated with physical or radiographic findings and/or laboratory evidence of involvement of extrapulmonary tissues, can occur as the direct result of initial infection or because of the reactivation of dormant foci. In endemic areas, 50% of AIDS patients demonstrate PDH as the first manifestation of their disease. PDH is characterized by fever (75% of patients), weight loss, chills, night sweats, enlargement of the spleen, liver, or lymph nodes, and anemia. Pulmonary symptoms occur in only one-third of patients and do not always correlate with the presence of infiltrates on chest roentgenogram. A clinical syndrome resembling septicemia is seen in approximately 25% to 50% of patients.[10]

Diagnosis

The diagnosis of histoplasmosis is made on the basis of histopathology, cultures, antigen detection, and serologic tests for *Histoplasma*-specific antibodies. Detection of single, ovoid cells 2 to 5 μm in diameter with narrow-based budding by direct examination or by histologic study of blood smears or tissues should raise strong suspicion of infection with *H. capsulatum* because colonization does not occur as with *Aspergillus* or *Candida* infection. In patients with acute self-limited histoplasmosis, extensive testing to verify the diagnosis may not be necessary.[33]

In most patients, serologic evidence (complement fixation test or immunodiffusion testing) remains the primary method in the diagnosis of histoplasmosis. Detection of *Histoplasma* antigen by enzyme immunoassay (EIA) in the urine, blood, or bronchoalveolar lavage fluid of infected patients provides rapid diagnostic information and is particularly useful in patients who are severely ill. The highest sensitivity is obtained by testing both urine and serum.[33] *Histoplasma* EIA has also been used to monitor the course of therapy and to detect relapses in patients with AIDS, and the clearance of antigen from serum and urine correlates with clinical efficacy during maintenance therapy.[33]

Treatment

④ Table 144-4 summarizes the recommended therapy for the treatment of histoplasmosis. In general, asymptomatic or mildly ill patients and patients with sarcoid-like disease do not benefit from antifungal therapy. In the vast majority of patients, low-inoculum exposure to *H. capsulatum* results in *mild* or *asymptomatic* pulmonary histoplasmosis. The course of disease generally is benign, and symptoms usually abate within a few weeks of onset. Therapy can be helpful in symptomatic patients whose conditions have not improved during the first month of infection. Fever persisting more than 3 weeks can indicate that the patient is developing progressive disseminated disease, which can be aborted by antifungal therapy. Whether antifungal therapy hastens recovery or prevents complications is unknown because it has never been studied in prospective trials. The goals of therapy are resolution of clinical abnormalities, prevention of relapse, and eradication of infection whenever possible, although chronic suppression of infection can be adequate in immunosuppressed patients, including those with HIV disease.[10] Such patients may also require longer durations of therapy and lifelong suppressive therapy if immunosuppression cannot be reduced.

Fluconazole remains a second-line agent for the treatment of histoplasmosis due to inferior outcomes as compared to itraconazole in patients with and without AIDS. Clinical data regarding the use of newer azoles are limited. *Histoplasma* isolates from patients who have relapsed following therapy with fluconazole retain susceptibility to itraconazole, posaconazole, and isavuconazole, but not voriconazole. Voriconazole was clinically inferior to itraconazole as an initial or step-down therapeutic regimen.[35,36] While both have activity against *Histoplasma*, posaconazole appears to be more active than itraconazole in the immune compromised and non-immune compromised mouse model of infection. Both agents have been used successfully in a few patients. Of note, the echinocandins have no activity against *Histoplasma*.

In regions experiencing high rates of histoplasmosis (> 5 cases/100 patient-years), itraconazole 200 mg/day orally is recommended as prophylactic therapy in HIV-infected patients. Fluconazole is not an acceptable alternative because of its inferior activity against *H. capsulatum* and its lower efficacy for the treatment of histoplasmosis.[10]

Although patients receiving secondary prophylaxis (chronic maintenance therapy) might be at low risk for recurrence of systemic mycosis when their $CD4^+$ T lymphocyte counts increase to greater than 100 cells/μL (0.1×10^9/L) in response to highly active antiretroviral therapy (HAART), the number of patients who have been evaluated is insufficient to warrant a recommendation to discontinue prophylaxis.

Evaluation of Therapeutic Outcomes

Response to therapy should be measured by resolution of radiologic, serologic, and microbiologic parameters and by improvement in signs and symptoms of infection. Although investigators are limited by the lack of standardized criteria to quantify the extent of infection, degree of immunosuppression, or treatment response, response rates (based on resolution or improvement in presenting signs and symptoms) of greater than 80% have been reported in case series in AIDS patients receiving varied dosages of amphotericin B. Rapid responses are reported, with the resolution of symptoms in 25% and 75% of patients by days 3 and 7 of therapy, respectively.

After the initial course of therapy for histoplasmosis is complete, lifelong suppressive therapy in some patients with oral azoles is recommended because of the frequent recurrence of infection. Relapse rates in AIDS patients not receiving maintenance therapy range from 50% to 90%.[10] Antigen testing can be useful for monitoring therapy since concentrations decrease with therapy and increase with relapse.

BLASTOMYCOSIS

Blastomycosis is a systemic fungal infection primarily caused by the *Blastomyces dermatitidis* complex, a dimorphic fungus that infects primarily the lungs. Patients, however, can present with a variety of pulmonary and extrapulmonary clinical manifestations. Pulmonary disease can be acute or chronic and can mimic infection with tuberculosis, pyogenic bacteria, other fungi, or malignancy. Blastomycosis can disseminate to virtually every other body organ, and approximately 40% of patients with blastomycosis present with skin, bone and joint, or genitourinary tract involvement without any evidence of pulmonary disease.[8,37]

Pulmonary infection probably occurs by inhalation of conidia, which convert to the yeast form in the lung. A vigorous inflammatory response ensues, with neutrophilic recruitment to the lungs followed by the development of cell-mediated immunity and the formation of non-caseating granulomas.

Epidemiology

The *Blastomyces dermatitidis* complex includes *B. dermatitidis* and *B. gilchristii*, although they are often referred to solely as *B. dermatitidis*. *B. dermatitidis* has been isolated from soil containing decayed vegetation, decomposed wood, and pigeon manure, frequently in association with warm, moist soil of wooded areas near fresh water. *B. dermatitidis* is endemic to the southeastern and south central states of the United States (especially those bordering on the Mississippi and Ohio River basins) and the Midwestern states and Canadian provinces bordering the Great Lakes and St. Lawrence River. Infection due to other rarer species occurs outside this endemic region, such as *B. helicus* in the western United States.[8,37] Although initial review of sporadic cases suggested that males with outdoor occupations that exposed them to soil were at greatest risk for blastomycosis, there is no sex, age, or occupational predilection for blastomycosis.[8,37]

Pathophysiology and Clinical Presentation

Colonization does not occur with *Blastomyces*.[8,37] *Pulmonary blastomycosis* is the most common manifestation, and can range from asymptomatic infection to acute pneumonia with or without respiratory failure to chronic disease. Typical symptoms of acute pulmonary infection include fever, shaking chills, and productive, purulent cough, with or without hemoptysis. The clinical presentation can be difficult to differentiate from other respiratory infections, including bacterial pneumonia, on the basis of clinical symptoms alone. Development of the acute respiratory distress syndrome (ARDS) is associated with high mortality.

Sporadic pulmonary blastomycosis can present as a more chronic or subacute disease, with low-grade fever, night sweats, weight loss, and productive cough that resembles tuberculosis rather than bacterial pneumonia. *Chronic pulmonary blastomycosis* is characterized by fever, malaise, weight loss, night sweats, chest pain, and productive cough. Patients often are thought to have tuberculosis and frequently have evidence of disseminated disease that can appear 1 to 3 years after the primary pneumonia has resolved. Reactivation of disease can occur in the lungs or as the focus of new infection in other organs.

In approximately 15% to 50% of patients, dissemination occurs, with the most common sites including the skin and bony skeleton, although less commonly the prostate, oropharyngeal mucosa, and abdominal viscera are involved. CNS disease, while exceedingly uncommon, is associated with the highest mortality rate.

Laboratory and Diagnostic Tests

The simplest and most successful method of diagnosing blastomycosis is by direct microscopic visualization of the large, multinucleated yeast with single, broad-based buds in sputum or other respiratory specimens following staining.[8,37] Culture growth is slow and can require up to 30 days to isolate and identify a small inoculum.

No reliable skin test exists to determine the incidence and prevalence of disease in endemic populations, and reliable serologic diagnosis of blastomycosis is not available. Quantitative antigen testing is available, with highest sensitivity from urine samples, although cross-reactivity with other endemic fungi (including *H. capsulatum*) results in a low specificity.[37]

Treatment

Non-HIV-Infected Patient

⑤In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment. However, consideration should be given to treating all infected individuals to prevent extrapulmonary dissemination. All individuals with moderate-to-severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy.

In patients with mild-to-moderate pulmonary blastomycosis, itraconazole is effective; however, in patients with moderately severe to severe pulmonary disease, the clinical presentation of the patient, the immune competence of the patient, and the toxicity of the antifungal agents are the main determinants of the choice of antifungal therapy (Table 144-5). In the case of disease limited to the lungs, cure might have occurred without treatment before the diagnosis is made. Regardless of whether or not the patient receives treatment, however, he or she must be followed carefully for many years for evidence of reactivation or progressive disease.[8,37]

TABLE 144-5

Therapy of Blastomycosis

Type of Disease	Preferred Treatment
Pulmonary[a]	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily (total dose 1.5-2.5 g) × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily, × total of 6-12 months
Mild-to-moderate disease	Itraconazole[b,d] 200 mg orally three times daily for 3 days, then 2 00 mg twice daily, for a total of 6 months[b]
CNS disease	*Induction:* Lipid formulation of amphotericin B 5 mg/kg IV daily × 4-6 weeks, followed by an oral azole as consolidation therapy *Consolidation:* Fluconazole[d] 800 mg orally daily, or itraconazole[d] 200 mg two or three times orally daily, or voriconazole[d] 200-400 mg orally twice daily, for ≥ 12 months and until resolution of CSF abnormalities
Disseminated or Extrapulmonary Disease	
Moderately severe to severe disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[b] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, followed by itraconazole[c,d] 200 mg orally three times daily for 3 day s, then 200 mg twice daily × 6-12 months. Treat osteoarticular disease with 12 months of antifungal therapy Most clinicians prefer to step-down to itraconazole[d] therapy once the patient's condition improves
Mild to moderate	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 2 00 mg once or twice daily × ≥12 months. Treat osteoarticular disease with 12 months of antifungal therapy
Immunocompromised Host (Including Patients with AIDS, Transplants, or Receiving Chronic Glucocorticoid Therapy)	
Acute disease	Lipid formulation of amphotericin B 3-5 mg/kg IV daily or amphotericin B[a] 0.7-1 mg/kg IV daily × 1-2 weeks or until improvement is noted, then give suppressive therapy for a total of at least 12 months of therapy
Suppressive therapy	Itraconazole[c,d] 200 mg orally three times daily for 3 days, then 200 mg twice daily for a total of at least 12 months of therapy; lifelong suppressive therapy with oral itraconazole[d] 200 mg daily may be required for immunosuppressed patients in whom immunosuppression cannot be reversed, and in patients who experience relapse despite appropriate therapy

[a] In the immunocompetent host, acute pulmonary blastomycosis can be mild and self-limited and may not require treatment.

[b] Desoxycholate amphotericin B.

[c] Serum levels of itraconazole should be determined after the patient has received itraconazole for ≥2 weeks, to ensure adequate drug exposure.

[d] Azoles should not be used during pregnancy.

AIDS, acquired immunodeficiency syndrome.

Data from Reference 8.

Some authors recommend azole therapy for the treatment of self-limited pulmonary disease, with the hope of preventing late extrapulmonary disease; however, data supporting the efficacy of these regimens are lacking.[8,37] Itraconazole 200 to 400 mg/day demonstrated 90% efficacy as a first-line agent in the treatment of non-life-threatening non-CNS blastomycosis, and for compliant patients who completed at least 2 months of therapy, a success rate of 95% was noted. No therapeutic advantage was noted with the higher (400 mg) dosage as compared with patients treated with 200 mg.[38]

All patients with disseminated blastomycosis, as well as those with extrapulmonary disease, require therapy. Amphotericin B is recommended for patients with overwhelming or life-threatening disease, CNS infection, and treatment failures.[8,37] Lipid preparations of amphotericin B have largely replaced conventional amphotericin B for treatment of blastomycosis, despite their higher cost, due to their decreased renal toxicity. Surgery has only a limited role in the treatment of blastomycosis.

HIV-Infected Patient

For unclear reasons, blastomycosis is an uncommon opportunistic disease among immunocompromised individuals, including AIDS patients; however, blastomycosis can occur as a late (CD4 lymphocytes< 200 cells/mm^3 [0.2 × 10^9/L]) and frequently fatal complication of HIV infection. In this population, overwhelming disseminated disease with frequent involvement of the CNS is common.[8,37] Following induction therapy with amphotericin B (total cumulative dose of 1 g), HIV-infected patients should receive chronic suppressive therapy with an oral azole antifungal for at least a year and until they are on effective antiretroviral therapy with a CD4+ T-cell count > 150 cells/μL (0.15 × 10^9/L).[8,37]

COCCIDIOIDOMYCOSIS

Epidemiology

Coccidioidomycosis is caused by infection with *Coccidioides immitis* and *Coccidioides posadasii,* dimorphic fungi found in the southwestern and western United States, as well as in parts of Mexico and South America. In North America, the endemic regions encompass the semiarid areas of the southwestern United States from California to Texas known as the Lower Sonoran Zone, where there is scant annual rainfall, hot summers, and sandy, alkaline soil. *Coccidioides* grows in the soil as a mold, and mycelia proliferate during the rainy season. During the dry season, resistant arthroconidia form and become airborne when the soil is disturbed.

Although generally considered to be a regional disease, coccidioidomycosis has increased in importance in recent years because of the increased tourism and population in endemic areas, the increased use of immunosuppressive therapy in transplantation and oncology, and the AIDS epidemic. Although there is no racial, hormonal, or immunologic predisposition for acquiring primary disease, these factors affect the risk of subsequent dissemination of disease (Table 144-6).[39]

TABLE 144-6

Factors for Severe, Disseminated Infection with Coccidioidomycosis

Race (Filipino and African American ancestry)
Pregnancy (especially when infection is acquired or reactivated in the second or third trimester)
Male gender
Neonates
Compromised cellular immune system, including • AIDS patients • Patients receiving corticosteroids, immunosuppressive agents, or chemotherapy

AIDS, acquired immune deficiency syndrome.

Data from Reference 39.

Pathophysiology

When individuals come in contact with contaminated soil during ranching, dust storms, or proximity to construction sites or archeological excavations, arthroconidia are inhaled into the respiratory tree, where they transform into spherules, which reproduce by cleavage of the cytoplasm to produce endospores. The endospores are released when the spherules reach maturity. Similar to histoplasmosis, an acute inflammatory response in the tissue leads to infiltration of mononuclear cells, ultimately resulting in granuloma formation.[39]

Clinical Presentation

Coccidioidomycosis encompasses a spectrum of illnesses ranging from primary uncomplicated respiratory tract infection that resolves spontaneously to progressive pulmonary or disseminated infection.[39] Initial or primary infection almost always involves the lungs. Although approximately one-third of the population in endemic areas is infected, the average incidence of symptomatic disease is only approximately 0.43%.

Signs and Symptoms

Primary Coccidioidomycosis ("*Valley Fever*"): Approximately 60% of infected patients have an asymptomatic, self-limited infection without clinical or radiological manifestations. Most of the remaining 40% of patients exhibit non-specific symptoms that are often indistinguishable from ordinary upper respiratory infections, including fever, cough, headache, sore throat, myalgias, and fatigue that occur 1 to 3 weeks after exposure to the pathogen. More commonly, a diffuse, mild erythroderma or maculopapular rash is observed. Patients can have pleuritic chest pain and peripheral eosinophilia.

A fine, diffuse rash can appear during the first few days of the illness. Primary pneumonia can be the first manifestation of disease, characterized by a productive cough that can be blood-streaked, as well as single or multiple soft or dense homogeneous hilar or basal infiltrates on chest roentgenogram. *Chronic*, *persistent pneumonia, or persistent pulmonary coccidioidomycosis* (primary disease lasting more than 6 weeks) is complicated by hemoptysis, pulmonary scarring, and the formation of cavities or bronchopleural fistulas.

Necrosis of pulmonary tissue with drainage and cavity formation occurs commonly. Most parenchymal cavities close spontaneously or form dense nodular scar tissue that can become superinfected with bacteria or spherules of *Coccidioides*. These patients often have persistent cough, fevers, and weight loss.

Disseminated disease occurs in less than 1% of infected patients. The most common sites for dissemination are the skin, lymph nodes, bone, and meninges, although spleen, liver, kidney, and adrenal gland also can be involved. Occasionally, miliary coccidioidomycosis occurs with rapid, widespread dissemination, often in concert with positive blood cultures for *Coccidioides*. Patients with AIDS frequently present with miliary disease. Coccidioidomycosis in AIDS patients appears to be caused by reactivation of disease in most patients. Dissemination also is more likely if infection occurs during pregnancy, especially during the third trimester or in the immediate postpartum period.[39]

CNS infection occurs in approximately 16% of patients with disseminated coccidioidomycosis. Patients can present with meningeal disease without previous symptoms of primary pulmonary infection, although disease usually occurs within 6 months of the primary infection. The signs and symptoms are often subtle and non-specific, including headache, weakness, changes in mental status (lethargy and confusion), neck stiffness, low-grade fever, weight loss, and occasionally, hydrocephalus. Space-occupying lesions are rare, and the main areas of involvement are the basilar meninges.

The diagnoses of coccidioidomycosis generally utilizes identification or recovery of *Coccidioides* spp. from clinical specimens and detection of specific anticoccidioidal antibodies in serum or other body fluids.

Treatment

Goals of Therapy

Desired outcomes of treatment are resolution of signs and symptoms of infection, reduction of serum concentrations of anticoccidioidal antibodies, and return of function of involved organs. It would also be desirable to prevent relapse of illness on discontinuation of therapy, although current therapy is often unable to achieve this goal.

General Approach

⑥ Therapy for coccidioidomycosis is difficult, and the results are unpredictable. Guidelines[11] are available for treatment of this disease; however, optimal treatment for many forms of this disease still generates debate. The efficacy of antifungal therapy for coccidioidomycosis often is less certain than that for other fungal etiologies, such as blastomycosis, histoplasmosis, or cryptococcus, even when in vitro susceptibilities and the sites of infections are similar. The refractoriness of coccidioidomycosis can relate to the ability of *Coccidioides* spherules to release hundreds of endospores, maximally challenging host defenses.[39] Fortunately, only approximately 5% of infected patients require therapy.

Specific Agents Used for the Treatment of Coccidioidomycosis

Although there is continued disagreement among experts in endemic areas whether antifungal therapy in patients with uncomplicated early coccidioidal infection might shorten the course of illness or reduce the development of more serious complications, prospective randomized trials addressing this question are lacking. The excellent tolerability of oral azoles has lowered the threshold for deciding to treat primary infection, and clinicians should treat patients with significantly debilitating illness, those with extensive pulmonary disease, and with who are frail due to advanced age, concurrent diabetes or comorbidities.[11]

Azole antifungals, primarily fluconazole and itraconazole, have replaced amphotericin B as initial therapy for most chronic pulmonary or disseminated infections. Amphotericin B is now usually reserved for patients with respiratory failure because of infection with *Coccidioides* species, those with rapidly progressive coccidioidal infections, or women during pregnancy. Therapy often ranges from many months to years in duration, and in some patients, lifelong suppressive therapy is needed to prevent relapses. Specific antifungals (and their usual dosages) for the treatment of coccidioidomycosis include IV lipid formulations of amphotericin B (3-5 mg/kg/day), IV or oral fluconazole (usually 400-800 mg/day, although dosages as high as 1,200 mg/day have been used without complications), and itraconazole (200-300 mg orally twice daily or three times daily, as capsules or solution).[39] If itraconazole is used, measurement of serum concentrations can be helpful to ascertain whether oral bioavailability is adequate.

Given the efficacy and superior tolerability profile of the triazole antifungals, amphotericin B products are generally only recommended for patients refractory to or intolerant of other agents, or in those with rapid deterioration. Compared to amphotericin B deoxycholate, the lipid formulations of amphotericin B have not been studied extensively in coccidioidal infection but can offer a means of giving more drugs with less toxicity. Fluconazole probably is the most frequently used medicine given its tolerability, although high relapse rates have been reported in some studies. Itraconazole therapy resulted in superior response in patients with skeletal infection, and relapse rates in the overall study population were lower with itraconazole therapy than with fluconazole.[39,40] Posaconazole was effective treatment in patients with refractory infections. Its efficacy relative to other triazole antifungals is unknown.

Combination therapy with members of different classes of antifungal agents has not been evaluated in patients, and there is a hypothetical risk of antagonism. However, some clinicians feel that outcome in severe cases is improved when amphotericin B is combined with an azole antifungal. If the patient improves, the dosage of amphotericin B can be slowly decreased while the dosage of azole is maintained.[39]

Primary Respiratory Infection

Although most patients with symptomatic primary pulmonary disease recover without therapy, management should include follow-up visits for 1 to 2 years to document resolution of disease or to identify as early as possible evidence of pulmonary or extrapulmonary complications.

Patients with a large inoculum, severe infection, or concurrent risk factors (eg, HIV infection, organ transplant, pregnancy, or high doses of corticosteroids) probably should be treated, particularly those with high CF titers, in whom incipient or occult dissemination is likely. Because some racial or ethnic populations have a higher risk of dissemination, some clinicians advocate their inclusion in the high-risk group. Common indicators that are used to judge the severity of infection include weight loss (greater than 10%), intense night sweats persisting more than 3 weeks, infiltrates involving more than one-half of one lung or portions of both lungs, prominent or persistent hilar adenopathy, CF antibody titers of greater than 1:16, failure to develop dermal sensitivity to coccidioidal antigens, inability to work, or symptoms that persist for more than 2 months.[39]

Commonly prescribed therapies include currently available oral azole antifungals at their recommended doses for courses of therapy ranging from 3 to 6 months.[39] In patients with diffuse pneumonia with bilateral reticulonodular or miliary infiltrates, therapy usually is initiated with amphotericin B;

several weeks of therapy are required to produce clear evidence of improvement. Consolidation therapy with oral azoles can be considered at that time. The total duration of therapy should be at least 1 year, and in patients with underlying immunodeficiency, oral azole therapy should be continued as secondary prophylaxis.

Infections of the Pulmonary Cavity

Many pulmonary infections that are caused by *Coccidioides* are benign in their course and do not require intervention. In the absence of controlled clinical trials, evidence of the benefit of antifungal therapy is lacking, and asymptomatic infections generally are left untreated. Symptomatic patients can benefit from oral azole therapy, although recurrence of symptoms can be seen in some patients once therapy is discontinued. Surgical resection of localized cavities provides resolution of the problem in patients in whom the risks of surgery are not too high.[39]

Extrapulmonary (Disseminated) Disease

Nonmeningeal Disease

Almost all patients with disease located outside the lungs should receive antifungal therapy, which is usually initiated with 400 mg/day of an oral azole. Amphotericin B is an alternative therapy and can be necessary in patients with worsening lesions or with disease in particularly critical locations such as the vertebral column. Approximately 50% to 75% of patients treated with amphotericin B for nonmeningeal disease achieve a sustained remission, and therapy usually is curative in patients with infections localized strictly to skin and soft tissues without extensive abscess formation or tissue damage. The efficacy of local injection into joints or the peritoneum, as well as intra-articular or intradermal administration, remains poorly studied. Amphotericin B appears to be most efficacious when cell-mediated immunity is intact (as evidenced by a positive coccidioidin or spherulin skin test or low CF antibody titer). However, controlled trials that document these clinical impressions are lacking.[39]

Meningeal Disease

Fluconazole has become the drug of choice for the treatment of coccidioidal meningitis. A minimum dose of 400 mg/day orally leads to a clinical response in most patients and obviates the need for intrathecal amphotericin B. Some clinicians will initiate therapy with 800 or 1,000 mg/day, and itraconazole dosages of 400 to 600 mg/day are comparably effective. It is also clear, however, that fluconazole only leads to remission rather than cure of the infections; thus suppressive therapy must be continued for life. Ketoconazole cannot be recommended routinely for the treatment of coccidioidal meningitis because of its poor CNS penetration following oral administration. Patients who do not respond to fluconazole or itraconazole therapy are candidates for intrathecal amphotericin B therapy with or without continuation of azole therapy. The intrathecal dose of amphotericin B ranges from 0.01 to 1.5 mg given at intervals ranging from daily to weekly. Therapy is initiated with a low dosage and is titrated upward as patient tolerance develops.[39]

CRYPTOCOCCOSIS

Epidemiology

Cryptococcosis is a noncontagious, systemic mycotic infection caused by the ubiquitous encapsulated soil yeast *Cryptococcus*, which is found in soil, particularly in pigeon droppings, although disease occurs throughout the world, even in areas where pigeons are absent. Infections caused by *C. neoformans* var. *grubii* (serotype A) are seen worldwide among immunocompromised hosts, followed by *C. neoformans* var. *neoformans* (serotype D). On the other hand, *Cryptococcus gattii* (serotypes B and C) is geographically more restricted and in contrast to *C. neoformans*, rarely infects immunosuppressed patients, is not associated with HIV infection, and the infections are more difficult to treat. *C. gattii* is not associated with birds; its main reservoir was thought to be limited to certain species of eucalyptus tree. Until recently, it was most common in tropical and subtropical areas, such as Australia, South America, Southeast Asia, and central Africa, with the highest incidence in Papua New Guinea and Northern Australia, although infections occur in non-tropical areas such as North America and Europe. *C. gattii* emerged on Vancouver Island, British Columbia, Canada, in 1999, and subsequently spread to the Vancouver lower mainland, Washington state, and Oregon.[41,42]

Infection is acquired by inhalation of the organism. Immunocompromised patients are at elevated risk, including those with malignancies, diabetes mellitus, chronic renal failure, and organ transplants and those receiving immunosuppressive agents. In most developed countries, widespread use of

HAART has significantly decreased the incidence of cryptococcosis; however, the incidence and mortality of this infection are still extremely high in areas with limited access to HAART and a high incidence of HIV.[9,42]

Disease can remain localized in the lungs or can disseminate to other tissues, particularly the CNS, although the skin also can be affected. Hematogenous spread generally occurs in the immunocompromised host, although it also has been seen in individuals with intact immune systems.

Clinical Presentation

Primary cryptococcosis in humans almost always occurs in the lungs, although the pulmonary focus usually produces a subclinical infection. Symptomatic infections usually are manifested by cough, rales, and shortness of breath that generally resolve spontaneously. Cryptococcus can present as part of an immune reconstitution inflammatory syndrome (IRIS), a paradoxical worsening of preexisting infectious processes following the initiation of HAART in HIV-infected individuals. The symptoms of cryptococcal meningitis are nonspecific. Headache, fever, nausea, vomiting, mental status changes, and neck stiffness are generally observed. Less common symptoms include visual disturbances (photophobia and blurred vision), papilledema, seizures, and aphasia. Intracerebral mass lesions (cryptococcomas) are more common in *C. gattii* than in *C. neoformans*, presumably due to their different host immune responses.[42]

Laboratory Tests

With cryptococcal meningitis, the CSF opening pressure is elevated. There is a CSF pleocytosis (usually lymphocytes), leukocytosis, a decreased glucose concentration, and an elevated CSF protein concentration. There is also a positive cryptococcal antigen (detected by LA). The test is rapid, specific, and extremely sensitive, but false-negative results can occur. False-positive tests can result from cross-reactivity with rheumatoid factor and *Trichosporon beigelii. C. neoformans* can be detected in approximately 60% of patients by India ink smear of CSF, and it can be cultured in more than 96% of patients. Occasionally, large volumes of CSF are required to confirm the diagnosis.

The CSF parameters in patients with AIDS are similar to those seen in non-AIDS patients, with the exception of a decreased inflammatory response to the pathogen, resulting in a strikingly low number of leukocytes in CSF and extraordinarily high cryptococcal antigen titers.[42]

Treatment

The choice of treatment for disease caused by *C. neoformans* depends on both the anatomic sites of involvement and the host's immune status, and thus, treatment recommendations are divided into three specific risk groups: (a) HIV-infected individuals, (b) transplant recipients, and (c) non–HIV-infected and nontransplant hosts (Table 144-7).[9] The management of cryptococcosis includes systemic antifungal therapy, control of elevated intracranial pressure (ICP), and supportive care. When possible, immune defects should be addressed. Although no randomized clinical trials have been performed to address this, outcomes of treatment for CNS cryptococcosis (without mass lesions or hydrocephalus) appear to be similar for disease due to either *C. neoformans* or *C. gattii*.[41]

TABLE 144-7

Therapy of Cryptococcosis[a,b]

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Non-immunocompromised Patients (Non–HIV-Infected, Nontransplant)	
Meningoencephalitis *without* neurological complications, in patients in whom CSF yeast cultures are negative after 2 weeks of therapy	*Induction:* Amphotericin B[c,d] IV 0.7-1 mg/kg/day *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥4 weeks
Meningoencephalitis with neurological complications	*Induction:* Same as for patients without neurologic complications, but consider extending the induction therapy for a total of 6 weeks.

Follow all regimens with suppressive therapy	*Consolidation:* Fluconazole 400-800 mg orally daily × 8 weeks *Maintenance:* Fluconazole 200 mg orally daily × 6-12 months
Mild-to-moderate pulmonary disease (Non-meningeal disease)	Fluconazole 400 mg orally daily × 6-12 months
Severe pulmonary cryptococcosis	*Same as CNS disease* × *12 months*
Cryptococcemia (non-meningeal, non-pulmonary disease)	*Same as CNS disease* × *12 months*
HIV-infected Patients	
Primary therapy; induction and consolidation[d]	*Preferred regimen:* *Induction:* Amphotericin B[e] IV 0.7-1 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses for ≥2 weeks. *Alternative regimens, in order of preference:* Amphotericin Be IV 0.7-1 mg/kg IV daily × 4-6 weeks *or* liposomal amphotericin B 3-4 mg/kg IV daily[f] × 4-6 weeks *or* ABLC 5 mg/kg IV daily × 4-6 weeks *or* Amphotericin B IV 0.7 mg/kg IV daily, *plus* fluconazole 800 mg (12 mg/kg) orally daily × 2 weeks, followed by fluconazole 800 mg (12 mg/kg) orally daily × ≥8 weeks *or* Fluconazole ≥800 mg (1,200 mg/day is preferred) orally daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × 6 weeks *or* Fluconazole 800-1,200 mg/day orally daily × 10-1 2 weeks (a dosage ≥1,200 mg/day is preferred when fluconazole is used alone)[g]
Follow all regimens with suppressive therapy	*Consolidation:* Fluconazole 400 mg (6 mg/kg) orally daily × ≥8 weeks[h] Maintenance: Fluconazole 200 mg orally daily × ≥ 1 year[i]
Organ Transplant Recipients	
Mild-to-moderate non-CNS disease or mild-to-moderate symptoms without diffuse pulmonary infiltrates	Fluconazole 400 mg (6 mg/kg) orally daily × 6-12 months
CNS disease, moderately severe or severe CNS disease or disseminated disease without CNS disease, or severe pulmonary disease without evidence of extrapulmonary or disseminated disease	*Induction:* Liposomal amphotericin B 3-4 mg/kg IV daily,[f] or ABLC 5 mg/kg IV daily *plus* flucytosine 100 mg/kg/day orally in four divided doses × ≥2 weeks. If induction therapy does not include flucytosine, consider a lipid formulation of amphotericin B for ≥4-6 weeks of induction therapy. Consider the use of a lipid formulation of amphotericin B lipid formulation (6 mg/kg IV daily) in patients with a high-fungal burden disease or relapse of disease
Follow all regimens with suppressive therapy	Consolidation: Fluconazole 400-800 mg (6-12 mg/kg) per day orally for 8 weeks Maintenance: Fluconazole 200-400 mg per day orally for 6-12 months

---

[a] When more than one therapy is listed, they are listed in order of preference.

[b] See the text for definitions of induction, consolidation, suppressive/maintenance therapy, and prophylactic therapy.

[c] Deoxycholate amphotericin B.

[d] In patients with, or at risk of renal disease, lipid formulations of amphotericin B can be substituted for deoxycholate amphotericin B. Doses are liposomal amphotericin B 3-4 mg/kg IV daily, or amphotericin B lipid complex (ABLC) 5 mg/kg IV daily.

[e] Initiate HAART therapy 2-10 weeks after commencement of initial antifungal treatment.

[f] Liposomal amphotericin B has been given safely up to 6 mg/kg daily; could be considered in treatment failure or in patients with a high fungal burden.

[g] Or until cerebrospinal fluid (CSF) cultures are negative.

[h] Consider discontinuing suppressive therapy during HAART in patients with a CD4 cell count ≥100 cells/μL (0.1×10^9/L) and an undetectable or very low HIV RNA level sustained for ≥3months (with a minimum of 12 months of antifungal therapy). Consider reinstitution of maintenance therapy if the CD4 cell count decreases to <100 cells/μL (0.1×10^9/L).

[i] Drug level monitoring is strongly advised.

HIV, human immunodeficiency virus; IT, intrathecal.

Data from Reference 9.

Non-immunocompromised Patients

⑦ Prior to the introduction of amphotericin B, cryptococcal meningitis was an almost uniformly fatal disease; approximately 86% of patients died within 1 year. The use of large (1-1.5 mg/kg) daily doses of amphotericin B resulted in cure rates of approximately 64%. When amphotericin B is combined with flucytosine, a smaller dose of amphotericin B can be employed because of the in vitro and in vivo synergy between the two antifungal agents.[43] Resistance develops to flucytosine in up to 30% of patients treated with flucytosine alone, limiting its usefulness as monotherapy.[42] Combination therapy with amphotericin B and flucytosine has become standard therapy, will sterilize the CSF within 2 weeks of treatment in 60% to 90% of patients, and most immunocompetent patients will be treated successfully with 6 weeks of combination therapy.[43] Lipid formulations of amphotericin B are preferred because they increase the likelihood of completing the full course of therapy.[42] However, because of the need for prolonged IV therapy and the potential for renal and hematologic toxicity with this regimen, alternative regimens utilizing shorter (2 weeks) courses of amphotericin B followed by consolidation therapy with fluconazole for 8 weeks, then maintenance therapy with a lower dosage of fluconazole for 6 to 12 months has been advocated.[9]

For asymptomatic, immunocompetent hosts with isolated mild-to-moderate pulmonary disease and no evidence of CNS disease, careful observation can be warranted; in the case of symptomatic infection, fluconazole for 6 to 12 months is warranted. Patients with severe pulmonary disease should be treated with the same regimens as for CNS disease. Additionally, patients with non-CNS, non-pulmonary cryptococcosis, such as cryptococcemia, usually have disseminated disease and treatment regimens similar to those as for CNS disease are recommended.[9]

Despite low CSF concentrations of amphotericin B (2%-3% of those observed in plasma), the use of intrathecal amphotericin B is not recommended for the treatment of cryptococcal meningitis except in very ill patients or in patients with recurrent or progressive disease despite aggressive therapy with IV amphotericin B.[9]

The recommended management of raised ICP in cryptococcal meningitis (without hydrocephalus, a mass lesion, or a shift on computed tomography [CT] scan) has been repeated CSF removal by spinal tap. Those who do not respond and have ongoing raised ICP should have ophthalmologic monitoring for possible vision loss, and should be considered for ventriculoperitoneal shunt surgery. Neither corticosteroids (in the absence of IRIS) nor acetazolamide is recommended for management of raised ICP. Symptomatic, medically refractory mass lesions that may be compressing vital structures should be considered for surgical therapy.[9]

Immunocompromised Patients

Immunocompromised hosts with isolated severe pulmonary and extrapulmonary disease (including cryptococcemia) without CNS disease should be treated similar to non-immunocompromised patients with CNS disease. Induction regimens as short as 2 weeks in HIV-infected patients with CNS disease are effective. However, continuation of combination induction therapy is recommended in patients who have not improved or are deteriorating, or in those with anticipated/proven persistent positive CSF cultures. Non-HIV immunocompromised patients with CNS infection, such as solid organ transplant recipients, are generally managed with regimens similar to those recommended for patients with HIV.[9]

Organ Transplant Recipients

Cryptococcosis has been documented in an average of 2.8% of solid-organ transplant recipients. The median time to disease onset is 21 months after transplantation; 68.5% of the cases occur greater than 1 year after transplantation.

Induction therapy for solid organ transplant recipients with cryptococcal meningoencephalitis consists of liposomal amphotericin B or amphotericin B lipid complex (ABLC) plus flucytosine for at least 2 weeks. Fluconazole consolidation therapy should be administered for 8 weeks, and maintenance therapy should be continued for at least 6 to 12 months. Immunosuppressive management should include sequential or stepwise reduction of immunosuppressants, with consideration of lowering the corticosteroid dose first. Amphotericin B should be used with caution in transplant recipients and is not recommended as first-line therapy in this patient population due to the risk of nephrotoxicity in this population that frequently has reduced renal function. If used, the tolerated dosage of amphotericin B is uncertain, but 0.7 mg/kg daily is suggested with frequent renal function monitoring. Regardless of the agent utilized, all antifungal dosages need to be carefully monitored.[9]

HIV-Infected Patients

Primary antifungal prophylaxis for cryptococcosis is not routinely recommended in HIV-infected patients in the United States and Europe. However, in areas with limited HAART availability, high levels of antiretroviral drug resistance, and a high burden of disease, clinicians may wish to consider the use of either prophylactic therapy or a preemptive strategy with serum cryptococcal antigen testing for asymptomatic antigenemia.[9]

Early studies confirmed the benefit of early high-dose amphotericin B use, the usefulness of flucytosine added to amphotericin B for induction therapy, and the slight superiority of fluconazole over itraconazole for consolidation therapy.[43]

Amphotericin B formulations combined with flucytosine during the 2-week induction phase of therapy is the initial treatment of choice, as this regimen has been repeatedly validated in clinical trials.[44–46] Amphotericin B plus fluconazole and flucytosine plus fluconazole are non-preferred alternatives. In patients who cannot tolerate flucytosine, amphotericin B alone for 4 to 6 weeks is an alternative. After the initially successful 2-week induction period, consolidation therapy with fluconazole can be administered for 8 weeks. In patients in whom fluconazole cannot be given, itraconazole is an acceptable, albeit less effective, alternative.[9]

In HIV-infected patients, mortality is highly associated with elevated ICP (CSF opening pressure greater than 250 mm H_2O [2.5 kPa]). At the initiation of antifungal therapy, lumbar drainage should remove enough CSF to normalize the opening pressure. Patients initially should undergo daily lumbar punctures to maintain CSF opening pressure in the normal range. When the CSF pressure is normal for several days, the procedure can be suspended.[9] Adjunctive steroid treatment is not recommended.[47] Similarly, neither mannitol nor acetazolamide therapy provides any clear benefit in the management of elevated ICP.[9]

Suppressive (Maintenance) Therapy for Cryptococcal Meningitis in HIV-Infected Patients

Relapse of *C. neoformans* meningitis occurs in approximately 50% of AIDS patients after completion of primary therapy. Persistence of asymptomatic urinary *C. neoformans* has been documented in a high percentage of AIDS patients despite seemingly adequate courses of therapy for primary meningeal disease. The prostate appears to act as a sequestered reservoir of infection in these patients, resulting in systemic relapse.

Patients appear to be at low risk for recurrence of cryptococcosis when they have successfully completed a course of initial therapy for cryptococcosis, remain asymptomatic with regard to signs and symptoms of cryptococcosis, have received antifungal therapy for greater than 3 of the previous 6 months, have a serum cryptococcal antigen titer less than 1:512, or have a sustained increase (eg, greater than 6 months) in their CD4$^+$ T-lymphocyte counts to greater than 100 to 200 cells/μL (0.1×10^9-0.2×10^9/L) and an HIV viral load of less than 50 copies/mL (50×10^3/L).

After the completion of induction/consolidation phases of therapy, long-term chronic suppression with fluconazole (200 mg orally daily) should be continued for a minimum of one year. Maintenance therapy can be discontinued after one year in patients who have successfully completed primary therapy, are free of symptoms and signs of active cryptococcosis, and have been receiving HAART with a sustained CD4 cell count greater than 100 cells/mL (0.100×10^6/L) and an undetectable viral load sustained for at least 3 months.[9,43] One consideration regarding the initiation of HAART involves concern for immune reconstitution inflammatory syndrome (IRIS) in patients with AIDS not on antiretroviral therapy. In such patients, initiation of HAART may provoke an exuberant inflammatory response resulting in new/worsened symptoms, including possibly increasing intracranial pressure. Therefore, the initiation of HAART should be withheld during the induction phase of treatment, and started 2 to 10 weeks after the start of antifungal therapy. Corticosteroids may be necessary for major complications.[9,42]

CANDIDA INFECTIONS

Candida species are yeasts that exist primarily as small (4-6 μm), unicellular, thin-walled, ovoid cells that reproduce by budding. On agar medium, they form smooth, white, creamy colonies resembling staphylococci. Although there are more than 150 species of *Candida*, eight species—*C. albicans*, *C. tropicalis*, *Candida parapsilosis*, *C. krusei*, *Candida dublinensis*, *C. guilliermondii*, *C. lusitaniae*, and *C. glabrata*—are regarded as clinically important pathogens in human disease. Yeast forms, hyphae, and pseudohyphae can be found in clinical specimens.[48]

Pathophysiology

8 *C. albicans* is a normal commensal of the skin, female genital tract, and entire GI tract of humans. Therefore, the mere presence of hyphae or pseudohyphae in a clinical specimen is insufficient for the diagnosis of invasive disease. The majority of infections with *C. albicans* are acquired endogenously, although human-to-human transmission also can occur. Although the term *fungemia* refers to the presence of fungi in the blood, the most commonly isolated organism is *C. albicans*. Candidiasis can cause mucocutaneous or systemic infection, including endocarditis, peritonitis, arthritis, and infection of the CNS (Mucocutaneous infections caused by *Candida* are discussed in further detail in Chapter 143).

Adherence of *C. albicans* is important in the pathogenesis of oral candidiasis and subsequent colonization of the GI tract. Because evidence suggests that the GI tract is often the portal of entry for *Candida* in disseminated disease, factors that alter the adherence of *Candida* are crucial in the development of local and systemic infection. *C. tropicalis* adheres to intravascular catheters at a higher rate than *C. albicans*, a factor that may help to account for the increased incidence of systemic infections caused by this pathogen.

CANDIDEMIA AND ACUTE HEMATOGENOUSLY DISSEMINATED CANDIDIASIS

Epidemiology

Candidemia is the fourth most common BSI in US hospitals.[25] It is associated with high mortality, increased length of hospital stay, and significant economic burden.[49] Although patients with neutropenia are at high risk for IFIs, the use of antifungal prophylaxis and prompt initiation of antifungal therapy in persistently febrile patients with neutropenia who do not respond to antibiotics has resulted in a reduction in the frequency of *Candida* BSIs in this population.[7]

The most commonly encountered clinical species of *Candida* include *C. albicans, C. glabrata, C. tropicalis, C. parapsilosis, C. lusitaniae, C. krusei, and C. guilliermondii.* While *C. albicans* is still the most common species of *Candida* causing candidemia, its relative frequency is decreasing, while the frequency of the other, non-*albicans* species, especially *C. glabrata*, have increased.[15] The change in species is of concern clinically, as certain pathogens, such as *C. krusei* and *C. glabrata*, are intrinsically more resistant to commonly used triazole drugs.[15] Although risk factors for the development of *Candida* BSIs in ICU patients can be identified, factors that lead to the acquisition of specific species are still unclear.[26] The emergence of infections caused by *Candida auris*, a novel, pathogenic *Candida* species associated with a high (40%-60%) mortality is concerning. Several outbreaks of *C. auris*, which first appeared in 2009, have been reported in the United Kingdom and Spain. Most infections appear in patients with previous exposure to antifungals and has high potential for interhuman transmission.[50]

Patients' characteristics influence the distribution of *Candida* species: *C. krusei* and *C. tropicalis* in patients with hematologic malignancies, while *C. parapsilosis* is most common in children, neonates, and patients with central lines and receiving parenteral nutrition. Fungemia caused by *C. glabrata* is observed more commonly in adults older than 65 years of age, perhaps due to an increased rate of oral colonization with *C. glabrata* in the elderly, and also associated with antimicrobial use and severity of underlying illness.[15]

Pathophysiology

Candida is acquired via the GI tract, although organisms also can enter the bloodstream via indwelling IV catheters. Immunosuppressed patients, including those with lymphoreticular or hematologic malignancies, diabetes, and immunodeficiency diseases and those receiving immunosuppressive therapy with high-dose corticosteroids, immunosuppressants, antineoplastic agents, or broad-spectrum antimicrobial agents, are at high risk for IFIs (Table 144-8). Major risk factors include the use of CVCs, total PN, receipt of multiple antibiotics, extensive surgery and burns, renal failure and hemodialysis, mechanical ventilation, and prior fungal colonization. Patients who have undergone surgery (particularly surgery of the GI tract) are increasingly susceptible to disseminated candidal infections.[15,26,48]

TABLE 144-8

Risk Factors for Invasive Candidiasis

Colonization Corrected colonization index (CCI) ≥0.4[a] Colonization index (CI) ≥0.8[a] *Candida* spp. cultured from sites other than blood Candiduria
Antibiotic use Number of antibiotics prior to infection (per additional antibiotics) Use of two or more antibiotics Use of broad-spectrum antibiotics in previous 10 days
Surgery Surgery on ICU admission Gastro-abdominal surgery Abdominal drainage Elective surgery Cardiopulmonary bypass time >120 minutes Hickman catheter
Foreign devices Central venous catheter Triple lumen catheter in patients who have undergone surgery Bladder catheter
Renal failure and dialysis Prior hemodialysis Hemofiltration procedures Increased serum creatinine[b] New-onset hemodialysis within 3 days of admission to ICU Acute renal failure
Underlying disease/baseline characteristics Total PN Diabetes mellitus Apache II (per point) Signs of severe sepsis Diarrhea at any time Mechanical ventilation ≥10 days Hospital-acquired bacterial infection Bacterial peritonitis by ICU day 11 GI disease ICU length of stay Transferred from other hospital Use of corticosteroids Profound neutropenia (ANC <100/mm^3 [0.100 ×10^9/L])

[a] CI = the ratio of number of nonblood distinct body sites (dbs) heavily colonized with identical strains to the total number of dbs; CCI = the product of the CI and the ratio of the number of dbs showing heavy growth (≥10^5 CFU/mL [10^8 CFU/L]) to the total of dbs growing *Candida* spp.

[b] Serum creatinine >1.2 mg/dL (106 μmol/L) in females, >1.6 mg/dL (141 μmol/L) in males.

Data from Reference 26.

Clinical Presentation of Hematogenous Candidiasis

Dissemination of *C. albicans* can result in infection in single or multiple organs, particularly the kidney, brain, myocardium, skin, eye, liver, spleen, bone, and joints.[48]

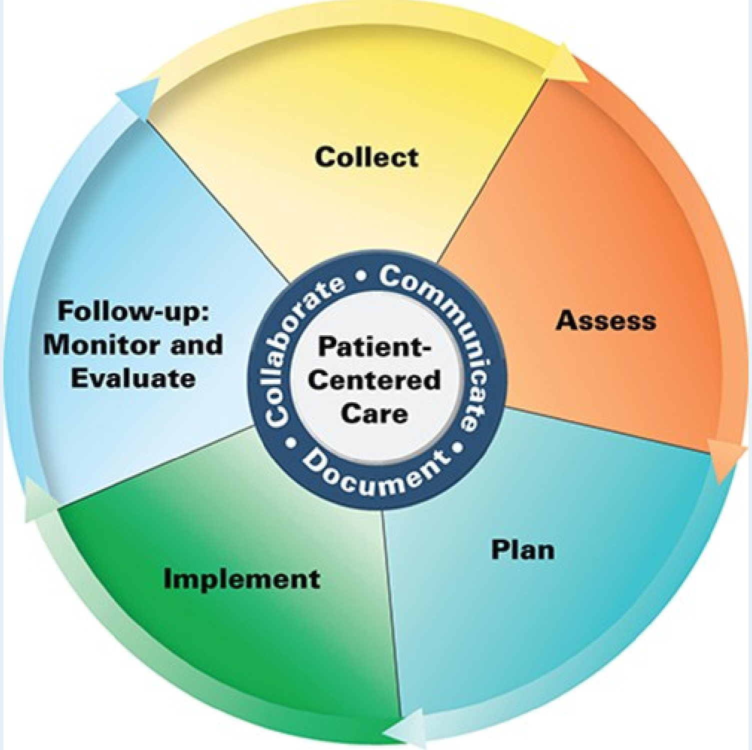
Laboratory Tests

The interpretation of positive surveillance cultures of the skin, mouth, sputum, feces, or urine is hampered by their occurrence as commensal pathogens and in distinguishing colonization from invasive disease. A rapid presumptive identification of *C. albicans* can be made by incubation of *Candida* in serum; formation of a germ tube (the beginning of hyphae, which arise as perpendicular extensions from the yeast cell, with no constriction at their point of origin) within 1 to 2 hours offers a positive identification of *C. albicans*. Unfortunately, *C. dubliniensis* also can produce a germ tube, and a negative germ tube test does not rule out the possibility of *C. albicans*, but further biochemical tests must be performed to differentiate between other non-*albicans* species.

Several rapid diagnostic methods are available at many hospitals, which can result in much more rapid identification of pathogens, including specific species, than with the use of traditional microbiological techniques. Matrix-assisted laser desorption/ionization time-of-flight intact cell mass spectrometry (MALDI-TOF-ICMS), a multiplex polymerase chain reaction (PCR) panel that includes 5 *Candida* species, and T2 Magnetic Resonance Assays provide rapid detection and identification of pathogenic *Candida* species.[48,51] Also available is the PNA fluorescence in situ hybridization (FISH) method, which uses fluorescein-labeled PNA probes that target *C. albicans* 26S rRNA for the identification of *C. albicans*, and a multiplex polymerase chain reaction (PCR) panel. The test has excellent sensitivity (99%-100%) and specificity (100%) in the direct identification of *C. albicans* from blood cultures.[52]

PATIENT CARE PROCESS

Patient Care Process for Candidemia



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, pregnant)
- Patient medical history (personal and family)
- Social history (eg, intravenous drug use)
- Current medications including non-prescription aspirin/NSAID use, herbal products, dietary supplements, and prior antifungal therapy
- Prior antifungal therapy (if applicable)
- Objective data
  - Blood pressure (BP), heart rate (HR), respiratory rate (RR), height, weight, O_2-saturation
  - Laboratory findings including white blood cells (WBC) with differential, hemoglobin (Hgb), platelets, serum creatinine (SCr), liver function tests (LFTs), blood cultures and susceptibility data
  - Objective confirmation of candidemia (+ blood cultures)

Assess

- Hemodynamic stability (eg, systolic BP 110 bpm, O_2-sat <90% [0.90], RR)
- Presence of
  - Ability/willingness to pay for antifungal agents
  - Ability/willingness to obtain laboratory monitoring tests
- Emotional status (eg, presence of anxiety, depression)

Plan*

- Empiric drug therapy regimen including specific antifungal agent(s), dose, route, frequency, and duration (see Table 144-9); and plan for step-down antifungal therapy, if appropriate, based on blood culture results (*Candida* species) of susceptibility testing, patient-specific factors (eg, LFTs, SCr, prior antifungal therapy, severity of illness)
- Monitoring parameters including efficacy including signs and symptoms of infection, temperature, BP, HR, WBC, daily blood cultures until negative cultures are obtained, transthoracic or transesophageal echocardiogram (TTE or TEE), ophthalmological examination, and safety (eg, LFTs, SCr, rash)
- Patient education (eg, purpose of treatment, drug-specific information)
- Referrals to other providers when appropriate (eg, ophthalmology)

Implement*

- Provide patient education regarding all elements of treatment plan
- Schedule follow-up (eg, labs, susceptibility data)

Follow-up: Monitor and Evaluate

- Resolution of symptoms (eg, shortness of breath, chest pain, limb swelling, redness, pain)
- Presence of adverse effects (three- to fivefold increase in LFTs, increased Scr, presence of rash)
- Patient adherence to treatment plan using multiple sources of information
- Reevaluate antifungal agent(s) to assess need for specific therapy (pathogen-directed, based on results of blood cultures) including step-down antifungal therapy, once final blood cultures and the results of susceptibility testing are available
- Reevaluate duration of therapy as blood culture and other laboratory data become available after the start of therapy (see text)

**Collaborate with patient, caregivers, and other healthcare professionals.*

Treatment

The list of risk factors for invasive candidiasis in critically ill patients is extensive, and trying to decipher which patients may benefit from antifungal prophylaxis or empirical therapy based on risk factors in an ICU is exceedingly difficult. In addition, the number of risk factors present in ICU patients changes over time, and the majority of ICU patients will have more than one risk factor. Clinically useful, practical predictive algorithms and “scoring systems” to identify high-risk patients early during their ICU admission have not proved successful thus far. To maximize its clinical utility as a decision-making tool, the ideal algorithm would identify high-risk populations (ones with a rate of invasive candidiasis of 10%-15%), providing clinicians with a means of administering prophylaxis to a minimal number of patients, while preventing the maximal number of invasive candidiasis cases.[26]

Although it is common practice in today’s standard of care to place indwelling catheters in patients for the administration of medications and parenteral nutrition (TPN), catheter-related infections are a common complication. These foreign bodies (especially triple lumen catheters) double as entry ports for normal skin flora or other nosocomial pathogens, and they provide a readily available site for the binding of pathogens via microbiotic biofilms. Their subsequent role as a source of BSIs is facilitated by frequent use, TPN, and the potential for contamination of catheters by medical staff who are colonized with *Candida* species. Most consensus recommendations urge removal of all existing tunneled CVCs and implantable devices, particularly in patients with fungemia caused by *C. parapsilosis*, which is frequently associated with catheters, as it has been associated with reduced mortality in adults, and a shorter duration of candidemia.[7] Arguments against the removal of all catheters in patients with candidemia include the prominent role of the gut as a source for disseminated candidiasis, the significant cost and potential for complications, and the problems that can be encountered in patients with difficult vascular access. However, in an individual patient it is often difficult to determine the relative contribution of gut versus catheter as the primary source of fungemia. The evidence for this recommendation is weakest in cancer patients with severe neutropenia and mucositis (eg, acute leukemia, stem cell transplant), in whom candidemia is almost always primarily of gut origin, and removal of CVCs is least likely to have an impact on mortality.[7]

Hematogenous Candidiasis

There is a high rate of mortality in non-neutropenic patients with fungal blood cultures. Delays in the initiation of antifungal therapy may significantly increase mortality.[53,54] Treatment of candidiasis should be guided by knowledge of the infecting species, the clinical status of the patient, and when available, the antifungal susceptibility of the infecting isolate. Therapy should be continued for 2 weeks after documented clearance of blood cultures, with resolution of all signs and symptoms of infection. All patients should undergo dilated fundoscopic examination within the first week of therapy. Susceptibility testing of the infecting isolate is a useful adjunct to species identification during selection of a therapeutic approach, since it can be used to identify isolates that are unlikely to respond to fluconazole or amphotericin B.[7] However, this is not currently available at many institutions.

Non-immunocompromised Patient

Prophylaxis

In ICUs, the use of fluconazole for prophylaxis or empirical therapy is common.[55] However, studies that demonstrated benefit in the prevention of invasive candidal BSIs did so either by using highly selective criteria or by studying patients in an unusually high-risk ICU setting, and the role of antifungal prophylaxis in the surgical ICU remains extremely controversial. For a study to demonstrate efficacy in clinical trials, the baseline rate of invasive candidiasis must be greater than 10%, and that prophylaxis must result in greater than fourfold reduction of disease. Although ICU-specific, greater than 10% rate of invasive candidiasis is generally found only in the setting of high-risk transplant patients (eg, patients undergoing liver transplantation), or in patients with a constellation of risk factors.[26] However, a significant benefit to prophylaxis in such high-risk, non-transplant patients has not been established.[56,57] Prophylactic antifungals may be indicated in patients with recurrent intestinal perforations and/or anastomotic leaks as these patients may be at high risk for invasive candidiasis and the use of empiric fluconazole may significantly decrease the incidence of infection.[58]

“Empirical” Therapy (Also Known as Preemptive Therapy)

The term “preemptive” antifungal therapy is often used to describe early antifungal therapy given to high-risk patients with persistent signs and symptoms and clinical, laboratory, or radiologic surrogate markers of infection but without mycological evidence of infection, or those heavily colonized with *Candida*.[26] Few data are available for assessing the role of antifungals as empirical therapy for *suspected* candidiasis in patients who do not yet exhibit a positive culture. The empiric use of fluconazole in one study, and micafungin in another, did not significantly improve outcomes; thus, preemptive/empiric use is not recommended at this time.[30,59]

Initial Antifungal Therapy in Non-Neutropenic Patients with Documented Candidemia, in Whom the Species Is Not Yet Identified and Results of Antifungal Susceptibility Testing Are Not Known

Azoles (fluconazole or voriconazole) and deoxycholate amphotericin B are similarly effective for the therapy of documented candidemia in non-neutropenic patients; however, fewer adverse effects are observed with azole therapy.[60,61] Echinocandins are at least as effective as amphotericin B, fluconazole, or isavuconazole in (primarily non-neutropenic) adult patients with candidemia.[62–66] Both fluconazole and the echinocandins are associated with fewer drug-related adverse events than amphotericin B preparations. Among the lipid-associated formulations of amphotericin B, liposomal amphotericin B (AmBisome) and ABLC (Abelcet) have been approved for use in proven cases of candidiasis. The lipid-associated formulations are less toxic but as effective as amphotericin B deoxycholate. Although the use of combination therapy (high-dose fluconazole plus amphotericin B) was superior to treatment with fluconazole alone, it was associated with a higher rate of nephrotoxicity, and the routine use of combination therapy in this patient population is not yet recommended.[67]

For empiric therapy in non-neutropenic adults, IDSA guidelines (Table 144-9) recommend use of an echinocandin or fluconazole (intravenous or oral) as initial therapy. Echinocandins are recommended for patients with moderately severe to severe illness, and patients with recent azole exposure. Patients may be transitioned to fluconazole (intravenous or oral) if their *Candida* isolates are known/likely to be susceptible to fluconazole (eg, *C.*

albicans, *C. parapsilosis*) in patients who are clinically stable, and in whom repeat negative blood cultures have been obtained. Fluconazole may be used initially in patients who are less critically ill, with no recent azole exposure, who are not at high risk for *C. glabrata* or with central nervous system or endocardial disease.[7]

TABLE 144-9

Antifungal Therapy of Invasive Candidiasis

Type of Disease and Common Clinical Manifestations	Therapy/Comments
Prophylaxis of Candidemia	
Non-neutropenic patients	Not recommended except for severely ill/high-risk patients in whom fluconazole IV/oral 400 mg daily should be used (see the text)
Neutropenic patients[1]	Fluconazole IV/oral 400 mg daily *or* itraconazole solution 2.5 mg/kg every 12 hours orally *or* micafungin 50 mg (1 mg/kg in patients under 50 kg) IV daily. The optimal duration of therapy is unclear but at a minimum should include the period at risk for neutropenia.
Solid-organ transplantation, liver transplantation	*Patients with key risk factors*[2]: FFluconazole 400 mg orally daily is preferred
Empirical (Preemptive) Antifungal Therapy	
Suspected disseminated candidiasis in febrile non-neutropenic patients	None recommended; data are lacking defining subsets of patients who are appropriate for therapy (see the text)
Suspected candidiasis in febrile neutropenic patients	A lipid formulation of amphotericin B, caspofungin, micafungin, voriconazole, isavuconazole, posaconazole, or itraconazole for duration of neutropenia
Initial Antifungal Therapy of Documented Candidemia and Acute Hematogenously Disseminated Candidiasis, Unknown Species	
Patients who are less critically ill and who have had no recent azole exposure[3]	*Remove existing central venous catheters when feasible plus fluconazole (loading dose of 800 mg [12 mg/kg], then 400 mg [6 mg/kg] daily) or an echinocandin.*[c] Treatment duration: 2 weeks after the last positive blood culture and resolution of signs and symptoms of infection
Patients with recent azole exposure, moderately severe or severe illness, or who are at high risk of infection due to *C. glabrata* or *C. krusei*	An echinocandin[c] Transition from an echinocandin to fluconazole is recommended for patients who are clinically stable and have isolates (eg, *C. albicans*) likely to be susceptible to fluconazole
Antifungal Therapy of Specific Pathogens	
C. albicans, C. tropicalis, and *C. parapsilosis*	Fluconazole IV/oral 6 mg/kg/day *or* an echinocandin[c]; transition to fluconazole is recommended in patients who are clinically stable and whose isolates are likely to be susceptible to fluconazole (eg, *C. albicans*); voriconazole (400 mg [6 mg/kg] twice daily × two doses then 200 mg [3 mg/kg] twice daily thereafter) is efficacious, but offers little advantage over fluconazole; it may be utilized as step-down oral therapy for selected cases of candidiasis due to *C. krusei* or

	voriconazole-susceptible *C. glabrata* *Patients intolerant or refractory to other therapy*[e]: Amphotericin B lipid complex IV 5 mg/kg/day Liposomal amphotericin B IV 3-5 mg/kg/day
C. krusei	An echinocandin[c]
C. lusitaniae	Fluconazole IV/orally 6 mg/kg/day
C. glabrata	An echinocandin[c] (transition to fluconazole or voriconazole therapy is not recommended without confirmation of isolate susceptibility)
Urinary candidiasis	*Asymptomatic disease:* Generally no therapy is required *Symptomatic or high-risk patients*[f]: Removal of urinary tract instruments, stents, and Foley catheters, +7-14 days therapy with fluconazole 200 mg orally daily *or* amphotericin B IV 0.3-1 mg/kg/day

1

Patients at significant risk for invasive candidiasis include those receiving standard chemotherapy for acute myelogenous leukemia, allogeneic bone marrow transplants, or high-risk autologous bone marrow transplants. However, among these populations, chemotherapy or bone marrow transplant protocols do not all produce equivalent risk, and local experience should be used to determine the relevance of prophylaxis.

2

Risk factors include re-transplantation, re-operation, renal failure requiring hemodialysis, transfusion of ≥40 units of cellular blood products including platelets, packed red blood cells, and auto transfusion; choledochojejunostomy, and Candida colonization in the perioperative period.[68]

4

Echinocandin = caspofungin 70 mg loading dose, then 50 mg IV daily maintenance dose, or micafungin 100 mg daily, or anidulafungin 200 mg loading dose, then 100 mg daily maintenance dose.

6

Patients at high risk for dissemination include neutropenic patients, low-birth-weight infants, and patients who will undergo urologic manipulation.

PO, orally.

Data from Reference 7.

Antifungal Therapy for Specific *Candida* Species

Since *C. glabrata* often demonstrate reduced susceptibility to fluconazole, treatment with echinocandins is recommended as initial therapy (pending the results of susceptibility testing), although there are successful treatment outcomes reported in response to fluconazole therapy of 6 to 12 mg/kg/day, and may be suitable in less critically ill patients.[7,69,70]

Regardless of the species of *Candida*, in the absence of metastatic complications of disease, antifungal therapy should be continued for 2 weeks after the last positive blood culture, and until there is resolution of signs and symptoms of infection. It is important to note when counting days of therapy that the days of treatment "begin" on the first day of documented clearance of *Candida* species from bloodstream, with the use of an effective antifungal agent to which the species is susceptible. As such, blood cultures should be repeated until negative. Existing central venous catheters should be removed when feasible, and all patients should undergo dilated retinal examination (preferably by an ophthalmologist) to rule out *Candida* endopthalmitis.[7]

In non-neutropenic adults, once the species of *Candida* has been identified, echinocandin therapy is recommended for the management of systemic *C. krusei* infections. *C. tropicalis* and *C. parapsilosis* may be treated with fluconazole at 6 mg/kg/day. Candidemia due to *C. parapsilosis* has increased in frequency among pediatric populations and appears to be associated with a lower mortality rate than other species of *Candida*. Since many, but not all isolates of *C. lusitaniae* are resistant to amphotericin B, fluconazole at 6 mg/kg/day is the preferred agent for treatment of this species. In patients with *C. parapsilosis* candidemia,[7] fluconazole is recommended, since MICs of echinocandins tend to be higher for *C. parapsilosis*. However, overall treatment success of candidemia or invasive candidiasis with echinocandins versus other agents was similar, and there was no difference in 30-day mortality between patients treated with fluconazole or an echinocandin.[71] The in vitro susceptibility of *C. auris* to antifungal agents is variable. However, while most isolates are susceptible to echinocandins, most are resistant to fluconazole, and ~40% of isolates are resistant to more than 2 classes of antifungal agents. An echinocandin is recommended as first-line therapy, with the addition of amphotericin B recommended in case of persistent fungemia or lack of clinical response.[50]

Expert opinion is divided regarding the optimal therapy of infections caused by *C. glabrata*. Guidelines recommend the use of an echinocandin until susceptibility is proven.[7] The severity of illness and choice of antifungal predict response in patients with *C. glabrata* fungemia, and the choice of antifungal (fluconazole or an echinocandin) does not influence mortality.[66,69] When fluconazole is dosed appropriately (Table 144-9), *C. glabrata* fluconazole susceptibility breakpoints are predictive of clinical and microbiological response.[70] Echinocandin therapy is independently associated with treatment success, but not survival, in invasive candidiasis due to *C. glabrata*.[66,69]

Immunocompromised Patients

In immunocompromised patients, the optimal agent, dose, and duration of therapy are unclear, and patients must be monitored carefully with serial blood cultures and careful physical examinations, particularly of the retina. Treatment guidelines in neutropenic patients generally approximate those from non-neutropenic hosts. Patients who experience prolonged neutropenia and persistent candidemia may benefit from administration of a recombinant cytokine (granulocyte colony-stimulating factor) that accelerates recovery from neutropenia.[7]

Prophylaxis

Recognition of the role of the GI tract in invasive *Candida* infections has led to efforts to decrease infections by prophylactic administration of topical or systemically absorbed antifungal agents in immunocompromised patients. The use of systemically absorbable agents such as azole antifungal agents appears to decrease the risk of IFIs.[7,72]

Several antifungal agents, including fluconazole (400 mg/day), posaconazole (200 mg three times daily), micafungin or caspofungin (50 mg daily) administered from the start of the conditioning regimen until day 75, can reduce the frequency of invasive *Candida* infections and decrease mortality in patients undergoing allogeneic bone marrow transplantation.[7,72]

Similarly, in less risk-selected patients with hematologic malignancies who are undergoing remission-induction chemotherapy, fluconazole, posaconazole, or caspofungin, during induction chemotherapy for the duration of neutropenia, are effective in preventing systemic infection and death caused by *Candida* species.[7,72]

For solid-organ transplant recipients, fluconazole or an echinocandin is recommended as postoperative antifungal prophylaxis for liver, pancreas, and small bowel transplant recipients at high risk of candidiasis.[7,68]

Widespread use of prophylactic fluconazole in all ICU patients is not warranted and may lead to an increase in resistance and adverse events. If utilized, prophylactic fluconazole should target high-risk patients with a presumed risk of invasive candidiasis of 10% to 15%.[7,26]

Empirical Therapy for Febrile Neutropenic Patients

In patients who have not been receiving antifungal prophylaxis, *Candida* spp. are the most likely cause of IFI. In patients receiving fluconazole prophylaxis, fluconazole-resistant *Candida* spp. (eg, *C. glabrata* and *C. krusei*) and invasive mold infections, particularly *Aspergillus* spp., are the most likely causes. A lipid formulation of amphotericin B, caspofungin, micafungin, voriconazole, isavuconazole, posaconazole, or itraconazole are recommended as suitable options for empiric antifungal therapy in neutropenic patients.[72] Guidelines recommend adding empiric antifungal therapy after 4 or more days of fever despite empiric antibiotic therapy in patients who are not receiving prophylaxis with mold-active agents and who are at high risk for mold infections (duration of neutropenia >10 days, allogeneic HSCT recipients, and high-dose corticosteroid treatment).[72]

For persistently febrile patients who have been receiving anti-mold prophylaxis, a different class of antifungal agent with activity against molds should be used for empiric therapy. The choice of the initial antifungal agent may vary based on an institution's experience (ie, epidemiology and susceptibility patterns) and patient risks for specific mold infections (eg, *Aspergillus* vs infections caused by the Mucorales). In patients with pulmonary nodules or nodular pulmonary infiltrates, invasive mold infection should be strongly suspected and treated. As fluconazole lacks activity against filamentous fungi, its use in patients at high risk for these pathogens should be avoided. In addition, clinicians need to consider that echinocandins are not active against *Cryptococcus* spp., *Trichosporon* spp., and filamentous molds other than *Aspergillus* spp. (eg, *Fusarium* spp.), nor are they active against the endemic fungi (*Histoplasma, Blastomyces,* and *Coccidioides* spp.).[73]

CANDIDURIA

Within the urinary tract, most common lesions are either *Candida* cystitis or hematogenously disseminated renal abscesses. *Candida* cystitis often follows catheterization or therapy with broad-spectrum antimicrobial agents. The diagnosis of *Candida* cystitis can be problematic because of the frequent presence of *Candida* pseudohyphae and yeast cells in urine specimens secondary to urethral colonization. The usefulness of urine colony counts or antibody coating techniques is questionable. The recovery of 10,000 organisms or visualization of both yeast and pseudohyphae from fresh midstream urine or from bladder urine obtained by single catheterization (not indwelling) is suggestive of genitourinary candidiasis. In most patients, the infection is asymptomatic and clears spontaneously without specific antifungal therapy.[7]

Initial therapy of candidal cystitis should focus on removal of urinary catheters whenever possible. Changing the catheter will eliminate candiduria in only 20% of patients, whereas discontinuation will eradicate *Candida* in 40% of patients. Asymptomatic candiduria rarely requires therapy. Therapy should be used in neutropenic patients, very low-birth-weight infants (<1500 g), and those who will undergo urologic manipulation, because of the risk of dissemination.[7]

Oral fluconazole 200 mg/day for 14 days hastens the time to a negative urine culture as compared with placebo treatment, but 2 weeks after the end of therapy, the frequency of a negative urine culture remains the same with both treatments.[74] Treatment should include removal of catheters and stents whenever possible plus 7 to 14 days of therapy. Bladder irrigation with amphotericin B (50 mg in 500 mL sterile water instilled twice daily into the bladder via a three-way catheter) is only transiently effective. Minimal quantities (less than 3%) of amphotericin B are absorbed systemically from the bladder.[7]

ASPERGILLOSIS

Saprophytic molds belonging to the *Aspergillus* spp. can be found around the world, of which, *Aspergillus fumigatus* is the most commonly observed pathogen, followed by *Aspergillus flavus.*

Invasive aspergillosis (IA) is the second most common IFI, with increasing incidence over the last 20 years along with the advances in the treatment of hematological malignancies. The infection most commonly affects immunocompromised patients and patients with acute myeloid leukemia (AML) and those who undergo allogeneic HSCT who develop GvHD are at highest risk. In the highest risk group, IA rates can reach 25%. The frequency of IA and infections caused by other molds have increased over the past 2 decades. Despite heightened awareness of the profiles of patients at risk, for *Aspergillus* infections, and despite the advent of liposomal formulations of amphotericin B, IA continues to be associated with extremely high mortality rates. The crude mortality approaches 75% in patients with AIDS and bone marrow transplant patients. Major target sites for primary invasive disease include the lungs and sinuses; frequently, secondary infections involve the central nervous system. The appropriate duration of treatment is based on the extent of the infection, response to therapy, and host factors.[75]

Epidemiology

Aspergillus is a ubiquitous mold that grows well on a variety of substrates, including soil, water, decaying vegetation, moldy hay or straw, and organic debris. Although more than 300 species of *Aspergillus* have been characterized, three species are most commonly pathogenic: *A. fumigatus*, *A. flavus*, and *A. niger.* The varying degrees of pathogenicity of each species depend on their relative geographic prevalence, conidial size and shape, thermotolerance, and production of mycotoxins. For example, transport of *A. fumigatus* conidia into the lungs is facilitated by their smaller diameter in comparison with *A. flavus* and *A. niger*.

9 The term *aspergillosis* may be broadly defined as a spectrum of diseases attributed to allergy, colonization, or tissue invasion caused by members of the fungal genus *Aspergillus*. A single satisfactory classification system for these disease entities is difficult because different populations of patients can develop the same type of infection. For example, osteomyelitis can result from local trauma or hematogenous dissemination in an immunocompromised host. Colonization in normal hosts can lead to allergic diseases ranging from asthma to allergic bronchopulmonary aspergillosis (BPA) or, rarely, invasive disease.[75]

Pathophysiology

Aspergillosis is acquired by inhalation of airborne conidia that are small enough (2.5-3 µm) to reach alveoli or the paranasal sinuses. Each conidiophore releases 10^4 conidia that remain suspended for long periods and are viable for months in dry locations. Although some authors advocate monitoring of hospital air for *Aspergillus* conidia, guidelines for interpreting results are not available. The use of high-efficiency particulate air (HEPA) filters in operating rooms and laminar flow rooms and removal of immunocompromised patients from hospital renovation sites can be helpful in preventing infection in this population.

Superficial or locally invasive infections of the ear, skin, or appendages often can be managed with topical antifungal therapy. Skin infections in patients with burn wounds, although uncommon, can progress to deep-tissue invasion despite the use of topical or parenteral antifungal agents. Risk factors for deep infection include extensive thermal injuries, malnutrition, cirrhosis, and previous infection with *Pseudomonas aeruginosa*.

Allergic manifestations of *Aspergillus* range in severity from mild asthma to allergic BPA. BPA, which is almost always caused by *A. fumigatus*, is characterized by severe asthma with wheezing, fever, malaise, weight loss, chest pain, and a cough productive of blood-streaked sputum. Following recurrent episodes of severe asthma, the disease usually progresses to fibrosis and bronchiectasis with granuloma formation. When *Aspergillus* conidia become trapped in the viscous mucus of asthmatic patients, BPA develops. The fungus grows, releasing toxins and antigens. The resulting host sensitization results in a variety of immune reactions. Early in the course of disease, an immunoglobulin E (IgE)-mediated (type I) immune reaction results in bronchospasm, eosinophilia, and immediate skin reactivity. The ensuing fibrosis and pulmonary infiltrates appear to be mediated by circulating or precipitating antibody complexes of IgG antibody, followed by granuloma formation and mononuclear infiltration because of a type IV delayed hypersensitivity reaction. Therapy is aimed at minimizing the quantity of antigenic material released in the tracheobronchial tree. Management of acute asthma attacks minimizes trapping of *Aspergillus* by bronchial secretions, and administration of corticosteroids clears lung infiltrates.[75] Antifungal therapy generally is not indicated in the management of allergic manifestations of aspergillosis, although some patients have demonstrated a decrease in their corticosteroid dose following therapy with itraconazole.[12]

Aspergilloma

Pulmonary aspergillomas are fungus balls arising in preexisting cavities because of tuberculosis, histoplasmosis, lung tumors, or radiation fibrosis, although occasionally no previous pulmonary disease is present. The diagnosis of aspergilloma generally is made on the basis of chest radiographs, on which aspergillomas appear as a solid rounded mass, sometimes mobile, of water density within a spherical or ovoid cavity and separated from the wall of the cavity by an airspace of variable size and shape. Patients generally experience chest pain, dyspnea, and sputum production. Hemoptysis is observed in 50% to 80% of patients, probably because of ulceration of the epithelial lining of the cavity with formation of granulation tissue, and hemoptysis is the cause of death in up to 26% of patients with aspergilloma. A poor prognosis is associated with increasing size or number of aspergillomas, immunosuppression (including corticosteroids), increasing *Aspergillus*-specific titers, underlying sarcoidosis, and HIV infection. Although *Aspergillus* can be cultured in only 50% to 60% of patients, precipitating antibodies are positive in virtually 100% of patients.

Invasive disease occurs rarely, and therapy therefore is controversial. There are no controlled clinical trials with which to guide therapy, and recommendations for treatment have been generated from uncontrolled trials and case reports. Concern regarding the risk of severe hemorrhage has led some clinicians to use aggressive surgical excision of aspergillomas or pulmonary resection in patients with hemoptysis. Complications, including bronchopulmonary fistulas, hemorrhage, empyema, and persistent airspace problems, have led to the recommendation that surgical intervention be reserved for patients with severe (greater than 500 mL per 24 hours) hemoptysis, however. Bronchial artery embolization has been used to occlude the vessel that supplies the bleeding site in patients experiencing hemoptysis. Unfortunately, bronchial artery embolization generally is unsuccessful or only temporarily effective. Collateral circulation eventually develops, supplying blood flow to the affected area, and hemoptysis often recurs;

consequently, reembolization is often unsuccessful. Bronchial artery embolization should be used as a temporizing procedure in a patient with life-threatening disease who might respond to more definitive therapy if hemoptysis is stabilized. Mild-to-moderate hemoptysis should be managed conservatively. Patients with spillage during surgery are recommended to receive a minimum of 4 weeks of therapy post-operatively. Hemoptysis generally ceases when the aspergilloma is eradicated.[12,75]

Invasive Aspergillosis

IA remains a disease of very high mortality: for example, in HSCT recipients with a diagnosis of invasive aspergillosis, the 3-month post HSCT mortality rate is 50% for autologous transplant recipients but approaches 75% for allogeneic HSCT recipients.[75]

Although exposure to *Aspergillus* conidia is nearly universal, impaired host defenses are required for the development of invasive disease. Phagocytes (neutrophils, monocytes, and macrophages) rather than antibodies or lymphocytes constitute the primary host defense system against invasive disease with aspergillosis. Macrophages prevent germination of conidia and also eradicate conidia, providing the first line of defense against invasive disease. Administration of corticosteroids appears to impair the killing of conidia by macrophages and to impair mobilization of neutrophils. Neutrophils halt hyphal growth and dissemination and kill mycelia, constituting a second line of defense. Prolonged neutropenia appears to be the most important predisposing factor to the development of IA, accounting for the high frequency of disease in patients with acute leukemia.[75]

Invasive disease with *Aspergillus* can arise de novo or from any of the allergic or colonizing forms of aspergillosis. Predisposing factors to the development of IA include glucocorticoid therapy, particularly following chronic administration or with higher dosages (30-200 mg/day of prednisone), cytotoxic agents, and recent or concurrent therapy with broad-spectrum antimicrobial agents. Patients with chronic hepatitis, alcoholism, diabetes mellitus, chronic granulomatous disease, leukopenia (less than 1,000 cells/mm^3 [1×10^9/L]), leukemia (particularly acute lymphocytic or myelogenous leukemia), lymphoma, and acute rejection of an organ transplant are also at a higher risk of invasive disease. Although rare, IA has been reported in apparently normal hosts.[75] For example, hospitalized patients with severe influenza, or more recently, SARS-CoV-2 infection, may develop superinfection due to *Aspergillus*.[76] Aspergillosis is an uncommon fungal infection in patients with AIDS, usually associated with other risk factors for infection, such as corticosteroid use and neutropenia.[12]

Clinical Presentation

The lung is the most common site of invasive disease. In the immunocompromised host, aspergillosis is characterized by vascular invasion leading to thrombosis, infarction, necrosis of tissue, and dissemination to other tissues and organs in the body. If bone marrow function returns, cavitation of the pulmonary lesion generally occurs, and the spread of infection can be halted. The progressive nature of the disease and its refractoriness to therapy are, in part, caused by the organism's rapid growth and its tendency to invade blood vessels.[75]

Clinical Presentation: Aspergillosis

Signs and Symptoms

Patients with invasive pulmonary aspergillosis (IPA) generally have blunted or non-specific signs and symptoms of infection due to impaired inflammatory responses. Patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs. The CNS, liver, spleen, heart, GI tract, pericardium, and other body sites are involved in a substantial minority of cases. In neutropenic patients with *Aspergillus* pneumonia, hyphae invade the walls of bronchi and surrounding parenchyma, resulting in an acute necrotizing, pyogenic pneumonitis. As a result, patients often present with classic signs and symptoms of acute pulmonary embolus: pleuritic chest pain, fever, hemoptysis, and friction rubs.[75]

Diagnosis

The diagnosis of aspergillosis is complicated by the presence of *Aspergillus* as a normal commensal in the human GI tract and respiratory secretions, and establishment of a definitive diagnosis of disease is difficult. The likelihood of IFIs is assessed on a scale of probability (possible, probable, proven) based upon host factors, clinical and microbiological criteria.[29] Demonstration of *Aspergillus* by repeated culture and microscopic examination of tissue provides the most firm diagnosis. A definitive diagnosis of IPA can be made by obtaining a biopsy of lung tissue; however, thrombocytopenia often limits clinicians' ability to perform this procedure. The appearance of *Aspergillus* in tissues varies with increasing host resistance from the normal vegetative hyphae found with necrotic tissue and exudate in the alveoli of immunocompromised hosts to the compact, tangled filaments (*granules*) observed in fungal balls. Identification of *Aspergillus* generally is based on the appearance of 2- to 4-μm-wide septate hyphae that are dichotomously branched at 45° angles. Sporulation is observed rarely in tissue. Although growth on Sabouraud dextrose or brain-heart infusion agar can be used for primary culture, bronchoscopy or bronchoalveolar lavage cultures are positive in only 40% of histopathologically identified specimens. Blood, CSF, and bone marrow cultures are rarely positive for *Aspergillus*.

The diagnosis is determined with the use of high resolution CT, in which IPA will manifest early on as "halo sign" (an area of low attenuation surrounding a nodular lung lesion, caused by edema or bleeding surrounding an ischemic area). In late IA nodular lesions, diffuse pulmonary infiltrates, consolidation, or ground glass opacities can be observed, and CT scans may demonstrate the crescent sign (an air crescent near the periphery of a lung nodule caused by contraction of infarcted tissue), while chest radiographs can demonstrate wedge-shaped, pleural-based infiltrates or cavities. These signs are not specific to IPA, however, as bacteria and other fungal infections may produce similar findings. CT abnormalities are best documented in neutropenic marrow transplant recipients and commonly precede plain chest radiograph abnormalities.[75]

Laboratory Tests

The diagnosis of aspergillosis, and other invasive mold infections, remains difficult. New laboratory methods that allow for early differentiation of IFIs due to *Aspergillus* species versus zygomycetes and other molds would be helpful in allowing clinicians in the earlier initiation of appropriate antifungal therapy. Although PCR-based testing is being performed in some centers, and appears promising, no FDA-approved method is commercially available.

The galactomannan test is an enzyme-linked immunosorbent assay (ELISA) (Platelia *Aspergillus* EIA test; Bio-Rad Laboratories) that detects galactomannan, an antigen released from *Aspergillus* hyphae upon invasion of host tissue. The clinical utility of this assay has been assessed in the clinical setting by sampling serum, BAL fluid, cerebrospinal fluid (CSF), and pleural fluid; however, the currently approved test is performed on serum. Additionally, while FDA-approved for use in the diagnosis of IA in HSCT recipients and in patients with leukemia; its usefulness in solid-organ transplant and pediatric populations needs to be established. In most patients, circulating antigen can be detected at a mean of 8 days before diagnosis by other means. The test has a sensitivity ranging from 40% to 90% and a specificity of approximately 90%; however, the sensitivity of the assay is decreased in patients receiving mold-active drugs on the day of sampling. False positives can occur, particularly in patients with other IFIs (including histoplasmosis and blastomycosis), receiving antibiotics such as amoxicillin–clavulanate, and in neonates. False negatives can occur during the concomitant use of antifungals, presumably because the level of galactomannan is related to the fungal burden. In addition, it is important to note that the utility of galactomannan testing in the setting of prophylaxis has not been defined.[12,75]

1,3-β-D-Glucan is a component of fungal cell walls that can be detected colorimetrically in clinical samples, including blood and bronchoalveolar lavage specimens, using a chromogenic variant of the limulus amoebocyte lysate assay. However, the current FDA-approved test (Fungitell; Associates of Cape Cod) is performed only on serum, and is nonspecific for *Aspergillus*. The 1,3-β-D-glucan test can be used to detect most fungi, with the exception of *Mucorales.* False positives are problematic with the test, with many processes and products associated with elevated levels, including hemodialysis with cellulose membranes, intravenous immune globulin or serum albumin administration, gastrointestinal surgery, and in other cases for unclear reasons.[77]

Treatment

Invasive Aspergillosis

Therapy for IA is far from optimal at this time in part because of the difficulties in establishing a diagnosis and in part because of a lack of truly effective antifungal agents. Administration of amphotericin B appears to decrease mortality from more than 90% to approximately 45%. These data, however, are difficult to interpret because many patients were diagnosed postmortem, or amphotericin B therapy was not administered until the patient had very advanced disease. Although early diagnosis and administration of antifungal therapy can result in higher response rates, correction of underlying immune deficits (in particular, return of neutrophil counts) is of paramount importance in eradication of infection.[75]

Until the diagnosis of aspergillosis can be determined more rapidly and definitively, empirical therapy must be instituted when invasive disease is suspected. In patients at highest risk for invasive disease (acute leukemia and bone marrow transplant recipients), the most important predisposing factors include prolonged severe neutropenia (less than 100 cell/μL [0.1×10^9/L] for more than 1 week), graft rejection, chronic administration of corticosteroids, and tissue damage from preexisting infection.[75]

Prophylaxis

As noted above in the discussion of prophylaxis for *Candida* infections in immunocompromised hosts, prophylaxis with azoles or echinocandins can reduce the incidence of aspergillosis in select high-risk populations. The incidence of IFIs following solid organ transplantation varies with the organ being transplanted and the epidemiology at individual centers. *Candida* and *Aspergillus* species are the leading causative agents, with the median time to onset following transplantation depending on the type of transplant. Several organizations have developed guidelines for the prevention of IFIs in patients with malignancies and in those undergoing solid organ or hematopoietic stem cell transplantation.[68,72,78]

Specific Therapy

The outcome of invasive aspergillosis (IA) continues to be associated with significant attributable mortality, especially in patients with hematological malignancies and in HSCT recipients. Older azole antifungal agents (miconazole, ketoconazole, and fluconazole) possess poor in vitro activity against *Aspergillus* species; however, newer triazoles (itraconazole, voriconazole, posaconazole, and isavuconazole) demonstrate improved activity both in vitro and in animal models of infection. Antifungal agents with in vitro activity against *Aspergillus* species include amphotericin B, the echinocandins, and the azoles itraconazole, voriconazole, posaconazole, and isavuconazole. Historically, high dosages (1-1.5 mg/kg/day) of deoxycholate amphotericin B were utilized for the treatment of suspected or proven invasive aspergillosis. Lipid formulations of amphotericin B are overall less nephrotoxic and at least as effective as amphotericin B, and they can be effective when amphotericin B is not.[79] Initial dosing of 10 mg/kg/day and 3 mg/kg/day of liposomal amphotericin B were equally effective, but there was decreased nephrotoxicity with the use of 3 mg/kg/day.[80]

Voriconazole has emerged as the drug of choice of most clinicians for primary therapy of most patients with IA, based on a pivotal study in which a randomized comparison of voriconazole and deoxycholate amphotericin B followed by other licensed antifungal agents for primary therapy for invasive aspergillosis demonstrated superior antifungal efficacy and improved survival at week 12 in the voriconazole arm.[81] Subsequently, isavuconazole has been approved for the primary treatment of aspergillosis, based upon the results of a double-blind, randomized, multinational trial in subjects with proven or probable invasive fungal disease caused by *Aspergillus* spp. or other filamentous fungi. Isavuconazole was well tolerated, with fewer drug-related adverse effects than voriconazole.[82] Posaconazole was shown to be non-inferior to voriconazole for the treatment of aspergillosis in a prospective, double-blind randomized trial.[83] In patients who are unable to tolerate or are not responding to azole therapy, or who are infected with azole-resistant isolates, amphotericin B can be used, with response measured by defervescence and radiographic clearing. To treat microfoci, therapy should be continued after resolution of clinical and radiographic abnormalities until cultures (if they can be obtained) are negative, and reversible underlying predispositions have abated.

Clinical response rather than any arbitrary total dose should guide duration of therapy. The optimal dosage or duration of treatment of invasive disease is unknown and dependent on the extent of disease, the response to therapy, and the patient’s underlying disease(s) and immune status. Response to therapy is largely related to the extent of aspergillosis at the time of diagnosis, and host factors, such as resolution of neutropenia and the return of neutrophil function, lessening immunosuppression, and the return of graft function from a bone marrow or organ transplant.[12]

Although caspofungin (and other echinocandins) have in vitro activity against *Aspergillus* species, echinocandins are unable to completely kill or inhibit *Aspergillus* species. Comparative randomized prospective trial data are not available for the echinocandins. Caspofungin is approved by the FDA for use as salvage therapy in patients who are refractory to or intolerant of other therapies such as conventional amphotericin B, lipid formulations of amphotericin B, and/or itraconazole.[12] However, for primary therapy of aspergillosis, response rates are lower with caspofungin than those obtained with voriconazole and amphotericin B.[84]

Given the continued high mortality of aspergillosis, combination therapy has been explored. However, while the advantages of combination therapy include the possibility of more rapid, synergistic killing, disadvantages include the possibility of antagonism, as well as increased cost and the increased risk of drug interactions and adverse effects. Combination therapy with voriconazole plus anidulafungin versus voriconazole alone was explored in a randomized, double-blind, placebo-controlled trial of patients with invasive aspergillosis. Combination therapy demonstrated a trend toward decreased 6-week survival compared to monotherapy, but did not achieve statistical significance (mortality rates 19.3% vs 27.5%, respectively).[85] Thus, there are as yet no firm recommendations regarding the use of combination therapy.[12]

Secondary Prophylaxis

The use of prophylactic antifungal therapy to prevent primary infection or reactivation of aspergillosis during subsequent courses of chemotherapy is recommended.[12] In granulocytopenic patients who recover from an episode of IA, the risk of relapse of aspergillosis during subsequent courses of chemotherapy is greater than 50%. Voriconazole reduced the incidence of invasive fungal function infection (mostly aspergillosis) to 6.7% when used as secondary prophylaxis in allogeneic stem cell transplant recipients with prior infection.[32]

TREATMENT OPTIONS FOR EMERGING PATHOGENS

The increased frequency of fungal pathogens that were once rare is gaining attention from the medical community. Mucormycosis, fusariosis, lomentosporiosis, and scedosporiosis are the most frequent cause of non-*Aspergillus* mold infections.[16]

Mucorales Infections

Mucormycosis, previously known as zygomycosis, is a term describing infections caused by fungi belonging to the order Mucorales. Permissive environmental conditions, selective antifungal pressure, and increased numbers of immunosuppressed patients have led to increased numbers of infections caused by the Mucorales, which include *Rhizomucor* spp., *Lichtheimia spp (formerly Absidia* spp.), *Rhizopus* spp., *Mucor* spp., and *Cunninghamella* spp. Prompt initiation of antifungal therapy is crucial, as treatment delays are associated with increased mortality.[86]

Of currently available systemic antifungals, only amphotericin B (including the lipid formulations) displays reliable activity against the Mucorales, while posaconazole and isavuconazole display variable activity, with wide MIC ranges.[16,87] Therapy with a liposomal or lipid-complex formulation of amphotericin B at a dosage of greater than or equal to 5 mg/kg/day, in addition to surgical debridement, is advocated by experts.[86,88]

Fusarium, Scedosporium, and *Lomentospora*

Unfortunately, the early presentation of *Fusarium, Scedosporium, and Lomentospora* infections often mimics that of aspergillosis. On histopathology, *Scedosporium* species resembles *Aspergillus* species with dichotomously branching, septate hyphae and has a tendency for invasion of vascular structures. These pathogens often demonstrate intrinsic to variable resistance to amphotericin B and are associated with high mortality rates. Interpretive CBPs for antifungal MICs and these pathogens are not available, and the optimal choice and duration of therapy is unknown. Global guidelines recommend the following strategies: for fusariosis, voriconazole (with or without a lipid amphotericin B product); for lomentosporosis, voriconazole plus terbinafine; and for scedosporiosis, voriconazole.[16,89]

Antifungal Therapy

Clinicians must have working knowledge of mechanism of action, spectrum of activity, dosing, and adverse effects of antifungals in order to provide appropriate recommendations for therapy. Dosing adjustments are needed for many antifungal agents in the setting of renal or hepatic dysfunction. A summary of the most common adverse effects of systemic antifungal agents are summarized in Fig. 144-3 and described in the text below.

The antifungal armamentarium for the treatment of IFIs includes (a) inhibitors of the fungal cell membrane such as polyenes (eg, amphotericin B) and azole antifungals, (b) inhibitors of DNA (5-flucytosine), and (c) inhibitors of cell wall biosynthesis (echinocandins).

Antifungal therapy generally includes one or more antifungal agents, depending on the severity of infection and the patients' immune status. Rarely are the agents used in combination. Often therapy is initiated with an IV agent such as an echinocandin or amphotericin B, and therapy is changed to an oral (azole) regimen as the patient's clinical status improves and oral therapy is tolerated.

Antifungal stewardship, particularly with integration of real-time decision support for the results of rapid diagnostic testing methods such as MALDI-TOF, may improve diagnosis and quality of care, while decreasing mortality and the cost of antifungal therapy.[93]

Amphotericin B

Amphotericin B remains the therapy of choice for many systemic fungal infections despite a lack of controlled clinical trials documenting the optimal dosage, duration of therapy, or relative efficacy of this agent in comparison with newer azole antifungal agents. During pregnancy, amphotericin B remains the treatment of choice for most fungal infections because azole antifungals are teratogenic.[94] The side effects of amphotericin B generally are categorized as acute (infusion-related) or long term. Amphotericin B commonly causes renal functional impairment, including decreased glomerular filtration rate, hypokalemia, hypomagnesemia, metabolic acidosis due to distal (or type 1) renal tubular acidosis (RTA), and polyuria due to nephrogenic diabetes insipidus. The nephrotoxicity associated with amphotericin B is usually reversible with discontinuation of therapy. However, recurrent renal dysfunction can occur if treatment is reinstituted. The risk of amphotericin B nephrotoxicity is increased by higher daily doses and concurrent therapy with other nephrotoxins, such as an aminoglycoside or cyclosporine. Salt loading (eg, 500-1,000 mL normal saline infusion) prior to dosing ameliorates/delays the onset of nephrotoxicity, and close monitoring and repletion of potassium and magnesium are necessary.[12,95]

Lipid Formulations of Amphotericin B

The use of deoxycholate amphotericin B is frequently associated with the development of induced nephrotoxicity. In an attempt to decrease the incidence of nephrotoxicity, three lipid formulations of amphotericin B have been developed and approved for use in humans: ABLC (Abelcet; Enzon Pharmaceuticals), ABCD (Amphotec; Intermune Pharmaceuticals), and liposomal amphotericin B (AmBisome; Gilead Pharmaceuticals). In these preparations, amphotericin B is incorporated into the phospholipid bilayer membrane rather than in the enclosed aqueous phase.[96]

The various lipid formulations of amphotericin B exhibit markedly different pharmacokinetics; however, whether these differences result in different outcomes in the treatment of specific types of infections (eg, CNS infections) is unclear. Although larger doses of these preparations are required to achieve similar pharmacologic effects as the deoxycholate form of amphotericin B, the toxicity appears to be much lower. Although the FDA-approved dosages of these agents are 5 mg/kg/day (ABLC), 3 to 6 mg/kg/day (ABCD), and 3 to 5 mg/kg/day (liposomal amphotericin B), the agents appear generally equipotent.[96] The optimal dose of these compounds for serious *Candida* infections is unknown; however, dosages of 3 to 5 mg/kg/day appear reasonable.[7]

Lipid formulations of amphotericin B, especially liposomal amphotericin B and amphotericin B lipid complex, are generally preferred over amphotericin B deoxycholate in clinical practice guidelines given their reduced potential for nephrotoxicity. There is up to a 6.6-fold increase in mortality in patients with amphotericin B– induced nephrotoxicity, and lipid formulations result in a significantly decreased incidence and severity of nephrotoxicity; liposomal amphotericin B may be less nephrotoxic than the ABLC.[96] Liposomal amphotericin B also results in significantly fewer infusion-related reactions than amphotericin B deoxycholate.[96,97]

Flucytosine

Flucytosine (also known as 5-flucytosine) is a fluorinated pyrimidine analog that is highly water-soluble. Patients with creatinine clearances of less than 40 mL/min (0.67 mL/s) should receive careful dosage adjustments. Peak serum concentrations (2 hours after an oral dose) should be monitored in all patients to maintain peak serum concentrations between 20 and 100 mg/L (155 and 775 μmol/L).[98,99]

Flucytosine generally is associated with few side effects in patients with normal renal, GI, and hematologic function, although rash, GI discomfort, diarrhea (5%-10%), and reversible elevations in hepatic enzymes are observed occasionally. In patients with renal dysfunction or concomitant amphotericin B therapy, leukopenia, thrombocytopenia, and (rarely) enterocolitis can occur. Myelotoxicity is well correlated with peak concentrations >100 mg/L (775 μmol/L).[98,99] Flucytosine is rapidly converted to 5-fluorouracil, which is toxic to mammalian cells, once taken up by fungal cells. Patients treated with flucytosine have detectable amounts of 5-fluorouracil in their serum and urine, although the mechanism of flucytosine toxicity is still incompletely understood. Flucytosine may be secreted into the GI tract, deaminated by intestinal bacteria, and reabsorbed as 5-fluorouracil.[98]

Flucytosine is used in combination with amphotericin B or fluconazole in the treatment of cryptococcosis or (less commonly) candidiasis. The rapid development of resistance to flucytosine, however, precludes its use as single-agent therapy. Mechanisms for drug resistance can include loss of deaminase and decreased permeability to the drug.[98]

Echinocandins

The echinocandins (caspofungin, micafungin, and anidulafungin) act as concentration-dependent, non-competitive inhibitors of BG synthase, an essential component of the cell wall of susceptible filamentous fungi that is absent in mammalian cells.

All echinocandins display linear pharmacokinetics following administration of IV dosages, and are degraded primarily by the liver (also in the adrenals and spleen) by hydrolysis and *N*-acetylation. Following initial distribution, echinocandins are taken up by red blood cells (micafungin) and the liver (caspofungin and micafungin) where they undergo slow degradation to mainly inactive metabolites, although two uncommon metabolites of micafungin possess antifungal activity. Degradation products are excreted slowly over many days, primarily through the bile. Among the echinocandins, anidulafungin is unique in being eliminated almost exclusively by slow chemical degradation rather than undergoing hepatic metabolism.

Echinocandins are available only as parenteral formulations, are not dialyzable, and do not require dosage adjustment in patients with renal insufficiency. They have minimal CSF penetration, largely because of their high protein binding and large molecular weights, although the clinical relevance of these findings can be disputed, given that several other antifungal agents (amphotericin B and itraconazole) are effective for the treatment of fungal meningitis despite low CSF concentrations. The echinocandins are well tolerated, although some patients may report histamine release resulting in rash, facial swelling, and itchiness.[100]

Azole Antifungal Agents

Adverse effects of azoles include GI disturbances (primarily nausea, vomiting, epigastric pain, and diarrhea), which appear to be more common in patients receiving ketoconazole and the solution formulation of itraconazole.[12] Although cyclodextrin is not absorbed following oral administration, use of the IV formulations of posaconazole and voriconazole is not recommended by the manufacturers because of concerns for potential nephrotoxicity secondary to accumulation of the cyclodextrin vehicle. This concern is likely not clinically relevant.[101] Fluconazole is well tolerated; intestinal complaints are the most frequently reported, followed by headaches and rash. Unlike ketoconazole, fluconazole does not inhibit testicular or adrenal steroidogenesis in healthy volunteers or hospitalized patients. Reversible alopecia occurs not infrequently and usually appears after several months of treatment with higher doses of fluconazole.[91] Azoles are potentially teratogenic and should be avoided in pregnant women.[94]

Azole antifungals have been implicated in idiosyncratic drug-induced liver injury with the incidence and pattern of injury varying between specific agents. The exact mechanism of toxicity has not been elucidated and there is varying level of evidence with regards to the effect of dose on the development of the toxicity. It is recommended that baseline liver function tests (LFTs) be obtained for patients being started on therapy with these agents and periodically monitored. In general, hepatotoxicity can occur at any time after initiation of the antifungal with most cases occurring in the first month of therapy. The liver injury is usually reversible with discontinuation of the offending agent. Substitution of the offending azole antifungal with a different azole antifungal can occur without impacting resolution of the toxicity.[91] Isavuconazole is less hepatotoxic than voriconazole.[82]

Azole antifungals are associated with QT prolongation as the result of cardiac hERG-mediated potassium channel blockade. However, azoles alone are not considered significant risk factors for serious drug-induced QT prolongation. Instead, the combination of azoles with other risk factors, such as other QT-prolonging medications, electrolyte abnormalities, and heart disease, is necessary to yield risk for serious QT prolongation. Isavuconazole is unique amongst the azoles in that it shortens the QT interval, and so is an option in cases of azole-induced QT prolongation.[92]

Itraconazole

Itraconazole is triazole antifungal with a broad spectrum of antifungal activity. Despite its marked structural similarity to ketoconazole, itraconazole differs in several important respects. Itraconazole appears to have greater specificity against fungal versus mammalian CYP, resulting in greater potency and a decrease in CYP-mediated side effects. In addition, itraconazole possesses in vitro activity against *Aspergillus* and *Sporothrix* species.

Like ketoconazole, the capsule formulation of itraconazole depends on the availability of low gastric pH for dissolution and absorption. Administration with food appears to enhance significantly the bioavailability of itraconazole capsules. Because itraconazole exhibits pH-dependent dissolution and absorption, absorption of the capsule formulation is impaired in patients receiving antacids or H_2-receptor antagonists and in patients with achlorhydria. Plasma concentrations of itraconazole following a single oral dose (capsules) in HIV-infected patients are approximately 50% lower than concentrations observed in healthy volunteers. The capsule formulation of itraconazole exhibits unpredictable oral bioavailability, particularly in subjects with hypochlorhydria and in patients with enteropathy caused by mucositis or GVHD of the gut. An oral suspension formulation of itraconazole was subsequently developed that uses cyclodextrin as a solubilizing vehicle to increase the solubility of the drug. The oral bioavailability of the solution is unaffected by alterations in gastric pH (such as concomitant omeprazole use) or in patients with enteropathy. The bioavailability of the oral solution is optimized in the fasting state.[102,103] A novel capsule formulation was developed which may result in more rapid and consistent attainment of therapeutic concentrations.[104]

Fluconazole

Fluconazole is a triazole antifungal agent with markedly different pharmacologic features than other marketed azole antifungals. The small molecular weight, low protein binding, and increased water solubility of fluconazole result in rapid, essentially complete absorption of drug following oral administration. Because fluconazole is excreted primarily (greater than 80%) as unchanged drug in the urine, dosage adjustments are necessary in patients with renal dysfunction.[90]

Voriconazole

The hepatic biotransformation of voriconazole is fairly complex and involves CYP2C19, CYP3A4, and CYP2C9, with most metabolism mediated through CYP2C19. Two of the CYPs involved in voriconazole metabolism (CYP2C19 and CYP2C9) exhibit genetic polymorphism; variability in the CYP2C19 genotype accounts for approximately 30% of the overall between subject variability in voriconazole pharmacokinetics. About 3% to 5% of white and African human populations are poor metabolizers, while 15% to 20% of Asian populations are poor metabolizers. Drug levels can be as much as fourfold greater in poor metabolizers than in individuals who are homozygous extensive metabolizers. Coadministration of voriconazole with drugs that are potent CYP450 enzyme inducers can significantly reduce voriconazole levels. Voriconazole drug interactions are dose-dependent, as they exhibit unpredictable non-linear pharmacokinetics; thus, drug interactions are more difficult to predict and manage.[92] Voriconazole is uniquely associated with phototoxicity. In addition, patients receiving long-term voriconazole are risk for development of skin cancer (primarily squamous cell carcinoma) and periostitis.[91,92]

The most common side effect of voriconazole is a reversible disturbance of vision (photopsia), which occurs in approximately 30% of patients but rarely leads to discontinuation of the drug. Symptoms tend to occur during the first week of therapy and decrease or disappear despite continued therapy. Patients experience altered color discrimination, blurred vision, the appearance of bright spots and wavy lines, and photophobia. Patients should be cautioned that driving can be hazardous because of the risk of visual disturbances. The visual effects are associated with changes in electroretinogram tracings, which revert to normal when treatment with the drug is stopped; no permanent damage to the retina has been demonstrated. Less common are visual and/or auditory hallucinations, which are associated with concentrations >5.5 μg/mL (mg/L; 15.7 μmol/L).[92]

Posaconazole

Posaconazole has a broad spectrum of antifungal activity, including *Aspergillus* and *Candida* species and variable activity against the Mucorales. Posaconazole was initially developed as an oral suspension for the prevention of IFIs in immunocompromised patients, including hematologic malignancy patients with prolonged neutropenia from chemotherapy as well as HSCT patients with GVHD.[23,24] However, to ensure adequate absorption, the suspension formulation had to be administered two to three times daily, with a high fat meal or a nutritional supplement. Most patients with GVHD, and many with chemotherapy-associated nausea or vomiting, mucositis or diarrhea, were unable to comply with the requirement for a fatty meal, resulting in decreased plasma concentrations of posaconazole and an increased risk of breakthrough fungal infection. The development of IV and delayed-release tablet formulations of posaconazole have circumvented these absorption issues and allows once daily oral administration of posaconazole following administration of a twice daily loading dose on the first day of therapy.[92]

Isavuconazole

Isavuconazole, is available both orally and IV, has a broad spectrum of activity against a number of clinically important yeasts and molds, including *Candida* spp., *Aspergillus* spp., *C. neoformans*, *Trichosporon* spp., and variable activity against the Mucorales. The most commonly reported adverse events, which are mild and limited in nature, include nausea, diarrhea, and elevated liver function tests. The potential advantage of this agent over other currently available broad-spectrum azole antifungals is a clinically useful alternative to voriconazole for the treatment of invasive aspergillosis, due to its lack of genetically determined variability in plasma levels, and more favorable and predictable drug interaction profile.[92]

Drug Interactions with Antifungal Agents

The interaction of azole antifungal agents with other CYP-metabolized drugs is well recognized. All azoles are inhibitors of the CYP3A4 enzyme system, and voriconazole and fluconazole additionally are inhibitors of CYP2C8/9 and CYP2C19. Apart from fluconazole (a substrate of CYP3A4 but mostly eliminated in the urine as unchanged drug) and posaconazole (metabolized by uridine diphosphate glucuronidation), the azoles appear to be metabolized almost entirely via the CYP3A4 subfamily. As expected, numerous clinically significant interactions have been documented with azole antifungals and a variety of other drugs. In most cases, the azole interferes with the metabolism of the other CYP-metabolized drug. Relative to ketoconazole and itraconazole, fluconazole appears to be intermediate in its ability to inhibit human cytochromes P450. The magnitude of fluconazole-induced inhibition of cyclosporine metabolism depends on the dosage of fluconazole. Isavuconazole appears to be a more modest inhibitor of CYP3A4 compared to voriconazole and posaconazole.[92,105]

Predictably, drugs such as rifampin, rifabutin, isoniazid, phenytoin, and carbamazepine, which are known to induce the activity of cytochromes P450, result in increased metabolism of the azole antifungals and can result in therapeutic failures. Increased dosages of azole antifungals can be required in patients receiving these combinations of drugs.[105]

Itraconazole is an inhibitor of intestinal Pgp. Significant increases in digoxin (a Pgp substrate) have been observed in patients receiving both agents concurrently. Interactions with other substrates of Pgp would be expected to occur.[105]

Echinocandins are not inducers of CYP enzymes, nor do they interact with Pgp, and are considered poor substrates of CYP3A4. Nevertheless, drug interactions are noted with caspofungin and cyclosporine and tacrolimus; the mechanism for these interactions is not yet known. Rifampin both inhibits (acutely) and induces (after chronic administration) caspofungin metabolism, and a dosage increase is recommended in patients receiving other enzyme inducers, such as efavirenz, nevirapine, phenytoin, dexamethasone, and carbamazepine. Although micafungin does not significantly affect the clearance (or area under the plasma- concentration vs time curve [AUC]) of tacrolimus, it increases the AUCs of sirolimus and nifedipine and decreases the clearance of cyclosporine.[100]

Therapeutic Drug Monitoring of Antifungal Agents

There is insufficient data to justify the routine use of therapeutic drug monitoring (TDM) for the prophylaxis or treatment of fungal infections with all antifungal agents. In addition, logistics, cost, and incorporation of TDM have yet to be worked out in modern prophylactic algorithms. However, under certain circumstances, serum or plasma concentration monitoring of select agents is warranted. Given the tremendous interpatient and intrapatient variability in voriconazole metabolism, TDM is warranted in most patients. Also, given the poor oral bioavailability of itraconazole capsules and posaconazole solution, monitoring is recommended, particularly in patients with GVHD of the gut, mucositis, or diarrhea, or poor oral intake or those receiving concomitant therapy with proton-pump inhibitors. Although the use of posaconazole tablets may result in a decreased need for TDM, patients with a higher weight and those experiencing diarrhea are more likely to have lower levels. Additional settings include patients susceptible to flucytosine toxicity, to document adequate oral absorption of poorly bioavailable azoles in cases of suspected treatment failure or concern about compliance or absorption, solubility and finally, when drug interactions that might reduce or accelerate the metabolism of azoles is suspected.[92,99] The need for isavuconazole TDM is undefined, as clinical experience has demonstrated limited pharmacokinetic variability and no clear correlations between concentrations and response or toxicity.[92] Recommendations regarding plasma concentration monitoring of antifungals are summarized in Table 144-10.

TABLE 144-10

Plasma Concentration Monitoring of Antifungal Agents

	Serum Concentration Monitoring Necessary?	Target Concentration Range	Timing of Sample
Echinocandins	No	NA	NA
Amphotericin B (including lipids)	No	NA	NA
Fluconazole	No	NA	NA
Isavuconazole	Unclear; appears to demonstrate limited pharmacokinetic variability and no clear thresholds for efficacy or toxicity have been elucidated	NA	NA
Itraconazole	Yes, to ensure absorption and efficacy	*Efficacy:* Prophylaxis: >0.5 μg/mL (mg/L; 0.7 μmol/L) Treatment: >1 μg/mL (mg/L; 1.4 μmol/L) *Toxicity:* <5 μg/mL (mg/L; 7 μmol/L)	Trough 7 days after initiation of therapy

Voriconazole	Probably yes—in all patients treated for IFI, altered liver function, potential drug–drug interactions, lack of response *Low* concentrations are associated with poor outcome; *high* concentrations are associated with adverse effects Variable metabolism due to non-linear PK and genetic variability in CYP2C19 → unpredictable dose-exposure relationship	*Efficacy:* Prophylaxis: trough >0.5-2 µg/mL (mg/L; 1.4-5.7 µmol/L) Treatment: trough >1-2 µg/mL (mg/L; 2.9-5.7 µmol/L) Concentrations >2.0 µg/mL (mg/L; 5.7 µmol/L) are associated with improved outcome; 2-5.5 µg/mL (mg/L; 5.7-15.7 µmol/L) is probably the best target *Toxicity:* concentrations >5.5 µg/mL (mg/L; 15.7 µmol/L) are associated with ↑ risk of neurotoxicity	Trough after 5-7 days therapy if no loading dose administered; 48 hours after administration of loading dose in critically ill patient (time to steady state is unpredictable due to nonlinear metabolism)
Posaconazole delayed release tablets	Maybe Outcomes (but not adverse events) correlate with higher plasma concentrations in prophylaxis and possibly treatment	*Efficacy:* Prophylaxis: >0.7 µg/mL (mg/L; 1 µmol/L) Treatment: Not well studied; concentrations >1.25 µg/mL (mg/L; 1.78 µmol/L) *Toxicity:* Correlation with toxicity poorly defined	Random level at SS (>7 days therapy). The long $t_{1/2}$ ensures little fluctuation in peaks and troughs at SS.
Flucytosine	Yes—high concentrations are associated with toxicity	*Toxicity:* “Peak” <80-100 µg/mL (mg/L; 620-775 µmol/L) *Efficacy:* Peak >20 µg/mL (mg/L; 155 µmol/L)	2 hours postdose “peak”, 3-5 days after initiation of therapy

SELF-ASSESSMENT QUESTIONS

1. In vitro susceptibility testing of antifungal agents:
    - A. Is available at most hospital clinical microbiology laboratories.
    - B. Reliably predicts clinical outcome, regardless of patient host factors.
    - C. Can alert the clinician to the presence of azole-resistant isolates of Candida.
    - D. Rely on the use of high temperatures and long incubation times, in order to induce hyphal formation.
    - E. Is utilized in practice mostly to inform therapeutic decisions in the treatment of invasive mold infections, like aspergillosis, since clinical breakpoints are established for filamentous fungi.
2. The in vitro spectrum of activity of echinocandins:
    - A. Includes typical pathogens encountered in the immunosuppressed patient, including Pseudomonas aeruginosa and methicillin-resistant Staphylococcus aureus.
    - B. Includes emerging fungal pathogens such as *Fusarium* and *Cryptococcus neoformans.*
    - C. May differ for various *Candida* species, depending on whether the mycelial or the yeast form of the pathogen is utilized in testing.
    - D. Includes many pathogenic fungi encountered in the immunosuppressed patient, including *C. albicans* and *Aspergillus* species.

E. Has demonstrated the rapid emergence of resistant strains of *C. albicans* in patients receiving greater than 2-week therapy.

3. SM is a 34-year-old woman currently being treated with voriconazole for invasive pulmonary aspergillosis caused by *Aspergillus fumigatus*. She develops a skin rash, which you believe due to voriconazole. Which of the following statements is most correct regarding appropriate antifungal therapy for SM?

A. An echinocandin should not be utilized, as its chemical structure is similar to that of azole antifungal agents such as fluconazole.

B. Therapy with an echinocandin (caspofungin or micafungin) is unlikely to cause a rash in this patient, as echinocandins are chemically unrelated to azole antifungal agents.

C. Micafungin should not be utilized as an alternative agent in this patient, as it demonstrates poor in vitro and in vivo activity against *A. fumigatus.*

D. Caspofungin could be utilized as an alternative agent in SM, as it demonstrates excellent in vitro and in vivo activity against Aspergillus fumigatus; however, SM is likely to experience a rash due to cross-sensitivity between azoles and echinocandin antifungals.

E. Micafungin would not be an appropriate alternative agent in this patient, as it demonstrates very poor efficacy in the treatment of pulmonary aspergillosis.

4. Blastomycosis is often mild and self-limited and may not require treatment. However, consideration should be given to treating which of the following infected individuals to prevent extrapulmonary dissemination?

A. All individuals with moderate-to-severe pneumonia

B. HIV-infected individuals

C. Individuals who are immunocompromised

D. Patients who have undergone hematopoietic stem cell transplantation

E. All of the above

5. RH is a 68-year-old male who is 6 months status post allogeneic hematopoietic stem cell transplantation, complicated by graft-versus-host disease. As his most recent chest radiograph indicates that he has invasive pulmonary aspergillosis that appears unresponsive to his current therapy with liposomal amphotericin B, his physician wishes to place RH on combination therapy with voriconazole and anidulafungin. Which of the following statements is most correct regarding RH’s therapy?

A. As RH’s amphotericin B regimen has resulted in an elevated serum creatinine, his anidulafungin dosage may need to be decreased, as anidulafungin is eliminated primarily via the kidneys.

B. The dosage of the patient’s tacrolimus will likely require adjustment, given the CYP3A4 inhibition of voriconazole.

C. Fluconazole would be a more appropriate choice than voriconazole to cover aspergillosis.

D. Prophylaxis with posaconazole would not have been recommended in this patient, and would not have potentially prevented the development of aspergillosis.

E. Combination therapy with voriconazole and anidulafungin is not recommended, as a clinical trial identified higher failure rates with this combination than with voriconazole monotherapy, suggesting a pharmacodynamic interaction.

6. When assessing infections caused by *Candida* species:

A. Candidemia is a rare cause of bloodstream infections in hospitals.

B. Mortality associated with infections due to *C. auris* appears to be quite high.

C. The proportion of infections caused by *C. albicans* has increased, while those caused by non-*albicans* species has decreased.

D. *C. glabrata* resistance to azoles is rare, and does not “cross” to other azoles.

E. Combination therapy is routinely recommended.

7. Visual changes observed in patients during voriconazole therapy:

A. Can cause permanent damage to the retina if therapy is continued for greater than 2 weeks.

B. Generally do not require discontinuation of the drug.

C. Are observed in less than 1% of patients.

D. Do not decrease or disappear despite continued therapy.

E. Are not associated with changes in electroretinogram tracings.

8. Plasma level monitoring of antifungals …

A. Rarely is necessary unless toxicity is observed.

B. Should probably be performed in all patients receiving long-term voriconazole therapy for aspergillosis.

C. Probably is needed for fluconazole, voriconazole, and caspofungin because the efficacy and toxicity of these agents correlate with peak levels.

D. Is only necessary in patients receiving fluconazole therapy for CNS infections.

E. Is not useful for voriconazole since neither efficacy nor toxicity is correlated with plasma concentrations.

9. According to current (2009) Infectious Diseases Society of America guidelines, initial antifungal therapy for Candida bloodstream infections:

A. Is similar for all *Candida* species.

B. Should always be initiated with fluconazole, due to its low cost and excellent safety profile.

C. Should always be initiated with echinocandins, since resistance rates of *Candida* species to fluconazole are high.

D. Should take into consideration whether the patient is unstable or severely immunocompromised, has a history of recent exposure to fluconazole or other azoles, or if non-*albicans* species are suspected.

E. Should be initiated as recommended in all patients, prior to obtaining positive blood cultures, if they are critically ill and not responding to antibacterial agents

10. All of the following statements regarding fungal disease are correct except:

A. Histoplasma capsulatum exists as mycelial forms at room temperature and yeast forms at body temperature.

B. All patients with early coccidioidal infections should be treated aggressively to prevent disseminated disease.

C. Blastomycosis often involves skin, bones, joints, and genitourinary tract.

D. Histoplasmosis may result in mediastinal fibrosis.

E. Pregnant women are at high risk for developing disseminated coccidioidomycosis.

11. All of the following are true regarding infections caused by *Candida* species except:

A. Infections are associated with a low rate of mortality when appropriate antifungal therapy is promptly initiated as soon as a patient becomes febrile.

B. While *C. albicans* remains the most common species causing infection, other species, including *C. glabrata* and *C. parapsilosis*, have become more common.

C. The role of antifungal prophylaxis in the surgical ICU remains extremely controversial.

D. Prophylactic antifungals are indicated in patients with recurrent intestinal perforations and/or anastomotic leak.

E. Alternatives to fluconazole should be considered when patients have a history of recent exposure to fluconazole or other azoles, and when non-*albicans* species are isolated.

12. In the treatment of coccidioidal meningitis:

A. Fluconazole 400 mg daily is the drug of choice.

B. Lifelong suppressive therapy must be followed.

C. Ketoconazole should not be recommended routinely due to its poor CNS penetration.

D. May require intrathecal amphotericin B therapy in patients who do not respond to fluconazole or itraconazole.

E. All of the above.

13. In patients with AIDS who have successfully completed primary therapy, lifelong maintenance therapy to prevent relapse of cryptococcal disease:

A. Is recommended for all patients after successful completion of primary induction therapy, with fluconazole 800 mg orally daily.

B. Is necessary and recommended for most patients, utilizing a low dosage of fluconazole (200 mg orally daily)

C. Is recommended for patients who are NOT on HAART therapy with a sustained CD4 cell count greater than 100 cells/mL (0.1×10^6/L) and undetectable viral load.

D. Ketoconazole is an effective and cost effective therapy.

E. Amphotericin B 1 mg/kg IV weekly is more effective and better tolerated than oral fluconazole 200 mg/day.

14. Prophylaxis of candidemia:

A. Is recommended in all non-neutropenic patients who are admitted to the ICU.

B. Is recommended in neutropenic patients for 1 week prior to and 6 months after they become neutropenic.

C. May be indicated in patients with recurrent intestinal perforations and/or anastomotic leaks.

D. Should never be utilized since the risk of antifungal resistance is increasing rapidly and our antifungal armamentarium is limited.

E. Is unnecessary, since prompt initiation of antifungal therapy in patients with clinical, laboratory, or radiologic surrogate markers of infection results in high rates of clinical success.

15. Risk factors for invasive candidiasis include all of the following except:

A. Long ICU stay.

B. Prior infection with *P. aeruginosa.*

C. The use of total parenteral nutrition (TPN).

D. The presence of acute renal failure.

E. The presence of central venous catheter.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** Antifungal susceptibility testing is not performed at most hospital clinical laboratories. Clinical breakpoints have only been established for selected antifungal agents and Candida. However, clinical failure may still occur despite in vitro susceptibility, depending on host and drug characteristics. See “Mycology” (Clinical Versus Microbial Resistance and Susceptibility Testing of Antifungal Agents) section.

2. **D.** Echinocandins are antifungal agents with a spectrum limited to Candida and Aspergillus. However, these are the most common pathogens encountered in clinical practice, especially in the immunosuppressed. See Tables 144-1 and 144-2 and “Mycology” (Epidemiology and Pathogenesis) section.

3. **B.** Echinocandins are a distinct class of agents from the azole antifungals, structurally, mechanistically, and in terms of common toxicities. While they are not preferred options for the treatment of invasive aspergillosis, they may be considered in patients refractory to or intolerant of other therapies. See “Aspergillosis” (Specific Therapy and Antifungal Therapy) sections.

4. **E.** All individuals with moderate-to-severe pneumonia, disseminated infection, or those who are immunocompromised require antifungal therapy. See “Blastomycosis” (Treatment) section.

5. **B.** Antifungal prophylaxis with posaconazole has been shown to significantly reduce the risk of aspergillosis in high-risk patients such as RH. While combination therapy with voriconazole and anidulafungin is controversial, it has demonstrated a trend towards improved survival. Anidulafungin is not predominantly renally eliminated and thus does not require renal dose adjustment, but voriconazole is a significant inhibitor of several CYP enzyme systems. See “Aspergillosis” (Specific Therapy and Antifungal Therapy) section.

6. **B.** *C. auris* is an emerging pathogen and has been associated with poor outcomes. The proportion of infections caused by non-albicans species has increased, most notably *C. glabrata*, which is complicated by its cross-resistance to the azole class of antifungals. See “Candida Infections” (Epidemiology) section.

7. **B.** Photopsia is a unique side effect to voriconazole, is common, and often decreases in severity or disappears with continued therapy. No permanent damage to the retina has been demonstrated. See “Antifungal Therapy” (Voriconazole) section.

8. **B.** Therapeutic drug monitoring (TDM) is rarely performed or indicated in patients receiving fluconazole, echinocandins, or amphotericin B products. TDM is warranted in most patients receiving voriconazole due to significant pharmacokinetic variability and correlations of clinical success and toxicity to levels. See “Therapeutic Drug Monitoring of Antifungal Agents” section.

9. **D.** Echinocandins are generally preferred as initial antifungal therapy for candidemia, but fluconazole may be appropriate in patients who are not severely ill, have no recent azole exposure, and who are unlikely to have a fluconazole-resistant isolate. See “Candida Infections” (Treatment) section.

10. **B.** Approximately 60% of patients infected with Coccidioides have an asymptomatic, self-limited infection. Patients with disease located outside the lung should generally receive therapy. Regarding isolated pulmonary disease, patients with a large inoculum, severe infection, or concurrent risk factors probably should be treated. See “Coccidioidomycosis” (Primary Respiratory Infection) section.

11. **A.** Unfortunately, mortality due to invasive candidiasis remains high, despite available antifungal therapies. This may be a reflection of the underlying comorbidity of patients who are at risk for developing candidiasis, such as critically ill surgical patients and those with significant immunocompromise. See “Candida Iinfections” (Epidemiology) section.

12. **E.** Fluconazole is the drug of choice for the treatment of coccidioidal meningitis. However, since fluconazole therapy only leads to remission, suppressive therapy must be continued for life. Patients with refractory infection may require intrathecal amphotericin B. See “Coccidioidomycosis” (Meningeal Disease) section.

13. **C.** Relapse is common in AIDS patients with cryptococcal meningitis, although certain patients appear to be at lower risk. Such patients include

those who have successfully completed therapy and have a sustained increase in their CD4 cell counts to greater than 100-200 cells and an undetectable HIV viral load. See “Cryptococcosis” (Suppressive (Maintenance) Therapy for Cryptococcal Meningitis in HIV-Infected Patient) section.

14. **C.** Prophylaxis of candidemia, especially in non-neutropenic patients, is controversial. Given the high mortality of invasive candidiasis, studies have attempted to delineate whether prophylaxis in certain patient populations could improve outcomes. Unfortunately, clinical trials in these settings have generally not been successful, although one small study did identify a benefit in patients with recurrent intestinal perforations and/or anastomotic leaks. See “Candida Infections” (Nonimmunocompromised Patient, Prophylaxis) section.

15. **B.** Major risk factors for invasive candidiasis include the use of central venous catheters, total parenteral nutrition, multifocal Candida colonization, and extensive surgery. While receipt of multiple antibiotics is also a risk factor for candidiasis, prior bacterial infection has not been identified as a strong risk factor for subsequent development of invasive candidiasis. See Table 144-8.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 145: Infections in Immunocompromised Patients

Scott W. Mueller; Douglas N. Fish

KEY CONCEPTS

KEY CONCEPTS

① An *immunocompromised host* is a patient with defects in host immune defenses that predispose to infection. Risk factors include neutropenia, immune system defects from disease or immunosuppressive drug therapy, compromise of natural host defenses, environmental contamination, and changes in normal flora of the host.

② Immunocompromised patients are at high risk for a variety of bacterial, fungal, viral, and protozoal infections. Bacterial infections caused by gram-positive cocci (staphylococci and streptococci) occur most frequently, followed by gram-negative bacterial infections caused by Enterobacterales and *Pseudomonas aeruginosa.* Fungal infections caused by *Candida* and *Aspergillus*, as well as certain viral infections (herpes simplex virus [HSV], cytomegalovirus [CMV]), are also important causes of morbidity and mortality.

③ Risk of infection in patients with neutropenia is associated with both the severity and duration of neutropenia. Patients with severe neutropenia (absolute neutrophil count less than 500 cells/mm^3 [0.5 × 10^9/L]) for greater than 7 to 10 days are considered to be at high risk of infection.

④ Fever (single oral temperature of greater than or equal to 38.3°C [100.9°F], or a temperature of greater than or equal to 38°C [100.4°F] for greater than or equal to 1 hour) is the most important clinical finding in patients with neutropenia and is usually the stimulus for further diagnostic workup and initiation of antimicrobial treatment. Infection should be considered as the cause of fever until proven otherwise. Usual signs and symptoms of infection may be altered or absent in patients with neutropenia. Appropriate empiric broad-spectrum antimicrobial therapy must be rapidly instituted to prevent excessive morbidity and mortality.

⑤ Empiric antimicrobial regimens for neutropenic infections should be based on patients' individual risk factors, as well as institutional infection and susceptibility patterns. The significant morbidity and mortality associated with gram-negative infections require that initial empiric regimens for treatment of febrile neutropenia have good activity against *P. aeruginosa* and Enterobacterales. Parenteral regimens most commonly recommended for initial inpatient treatment include monotherapy with an antipseudomonal β-lactam, or a combination regimen consisting of an antipseudomonal β-lactam plus an aminoglycoside. Low-risk patients may be successfully treated with oral antibiotics (fluoroquinolone plus amoxicillin-clavulanate), with the treatment setting determined by the patient's clinical status.

⑥ Patients with neutropenia who remain febrile after 3 to 5 days of initial antimicrobial therapy should be reevaluated to determine whether treatment modifications are necessary. Common antimicrobial modifications include addition of vancomycin (if not already administered) and antifungal therapy (amphotericin B, an echinocandin, or fluconazole). Therapy should be directed at causative organisms, if identified, but broad-spectrum regimens should be maintained during neutropenia.

⑦ The optimal duration of therapy for febrile neutropenia is controversial. The decision to discontinue antimicrobials is based on resolution of neutropenia, defervescence, culture results, and clinical stability of the patient.

⑧ Prophylactic antimicrobials are administered to patients with cancer who are expected to experience prolonged neutropenia, as well as to hematopoietic cell and solid-organ transplant recipients. Prophylactic regimens may include antibacterial, antifungal, antiviral, or antiprotozoal agents, or a combination of these, selected according to risk of infection with specific pathogens. Optimal prophylactic regimens should consider individual patient risk for infection and institutional infection and susceptibility patterns.

⑨ Patients undergoing hematopoietic cell transplant (previously referred to as hematopoietic stem cell transplant, or HCT) are at an extremely high risk of infection because of prolonged neutropenia following intensive chemotherapy with or without irradiation, while solid-organ transplant (SOT) recipients are at high risk because of prolonged administration of immunosuppressive drugs. Fungal (*Aspergillus*) and viral (CMV) infections are particularly troublesome in these populations, and prophylactic regimens directed against these pathogens are commonly used. When documented, these infections must be treated aggressively to optimize patient outcomes. Nevertheless, mortality rates are often high despite appropriate and aggressive antimicrobial therapy.

⑩ Immunocompromised patients must be continuously assessed for evidence of infection and response to antimicrobial therapy. Because a large number of antimicrobials may potentially be used, the occurrence of drug-related adverse effects must also be carefully assessed. Efforts should be directed at designing cost-effective treatment strategies that promote optimal patient outcomes.

BEYOND THE BOOK

BEYOND THE BOOK

Refer to “Chapter 143: Infection in an Immunocompromised Patient: Making a Rash Decision Level II” in Pharmacotherapy Casebook: A Patient-Focused Approach, 11e (may be obtained online through AccessPharmacy). After studying the patient presentation, briefly answer Questions 1 through 5 and the Follow-Up Case Questions 1 through 3 regarding patient Scarlet Hives’s febrile neutropenia following hematopoietic cell transplant. The purpose of this exercise is to gain experience in applying knowledge regarding assessment of possible infection in immunocompromised patients and development of an appropriate therapeutic plan based on clinical presentation, patient characteristics, type and severity of potential infection, past treatment history, and potential causative pathogens.

INTRODUCTION

An immunocompromised host is a patient with intrinsic or acquired defects in host immune defenses that predispose to infection. Advances in modern medicine have created more immunocompromised hosts than ever before. Historically, many of these patients died of their underlying diseases. Dramatic improvements in survival have been achieved by more aggressive therapy of underlying diseases and improved supportive care. However, because such aggressive therapy often renders patients profoundly immunosuppressed for long periods, opportunistic infections remain important causes of morbidity and mortality. This chapter focuses on risk factors for infection, common pathogens and infection sites, and prevention and management of suspected or documented infections in patients with cancer (including hematopoietic cell transplant [HCT] patients) and solid-organ transplant (SOT) recipients. Chapter 148, “Human Immunodeficiency Virus,” discusses infectious complications associated with human immunodeficiency virus (HIV) infection.

RISK FACTORS FOR INFECTION/EPIDEMIOLOGY

Numerous factors, such as underlying disease, immunosuppressive drug therapy, and antimicrobial administration, determine the immunocompromised host’s risk of developing infection (see Table 145-1). These same factors may also influence the epidemiology of the associated infections. Multiple risk factors are present concomitantly in many patients.

TABLE 145-1

Risk Factors and Common Pathogens in Immunocompromised Patients

Risk Factor	Patient Conditions	Common Pathogens

Neutropenia	• Acute leukemia • Chemotherapy	Bacteria: *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Escherichia coli*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, streptococci, enterococci
		Fungi: *Candida*, *Aspergillus*, Mucorales (*Mucor*)
		Viruses: Herpes simplex
Impaired cell-mediated immunity	• Lymphoma • Immunosuppressive therapy (steroids, cyclosporine, chemotherapy, CAR-T)	• Bacteria: *Listeria*, *Nocardia*, *Legionella*, Mycobacteria • Fungi: *Cryptococcus neoformans*, *Candida*, *Aspergillus*, *Histoplasma capsulatum* • Viruses: Cytomegalovirus, varicella-zoster, herpes simplex • Protozoa: *Pneumocystis jirovecii*
Impaired humoral immunity	Multiple myeloma	Bacteria: *S. pneumoniae*, *H. influenzae*, *N. meningitidis*
	Chronic lymphocytic leukemia	
	Splenectomy	
	Immunosuppressive therapy (steroids, chemotherapy, CAR-T)	
Loss of protective skin barriers	Venipuncture, bone marrow aspiration, urinary catheterization, vascular access devices, radiation, biopsies	• Bacteria: *S. aureus*, *S. epidermidis*, *Bacillus* spp., *Corynebacterium jeikeium* • Fungi: *Candida*
Mucous membranes	Respiratory support equipment, endoscopy, chemotherapy, radiation	Bacteria: *S. aureus*, *S. epidermidis*, streptococci, Enterobacterales, *P. aeruginosa*, *Bacteroides* spp., *Clostridioides difficile*
		Fungi: *Candida*
		Viruses: Herpes simplex
Surgery	Solid-organ transplantation	Bacteria: *S. aureus*, *S. epidermidis*, Enterobacterales, *P. aeruginosa*, *Bacteroides* spp., *C. difficile*
		Fungi: *Candida*
		Viruses: Herpes simplex
Alteration of normal microbial flora	• Antimicrobial therapy • Chemotherapy • Hospital environment	• Bacteria: Enterobacterales, *P. aeruginosa*, *Legionella*, *S. aureus*, *S. epidermidis*, *C. difficile* • Fungi: *Candida*, *Aspergillus*
Blood products, donor organs	Bone marrow transplantation	Fungi: *Candida*

	Solid-organ transplantation	• Viruses: Cytomegalovirus, Epstein–Barr virus, hepatitis B, hepatitis C • Protozo: *Toxoplasma gondii*

CAR-T, chimeric antigen receptor T cell.

Neutropenia

①②③ Neutropenia is defined as an abnormally reduced number of neutrophils circulating in peripheral blood. Although exact definitions of neutropenia can vary, an absolute neutrophil count (ANC) of less than 1,000 cells/mm^3 (1.0 × 10^9/L) indicates a reduction sufficient to predispose patients to infection.[1–3] ANC is the sum of the absolute numbers of both mature neutrophils (polymorphonuclear cells [PMNs], also called *polys* or *segs*) and immature neutrophils (*bands*). The absolute number of PMNs and bands is determined by dividing the total percentage of these cells (obtained from the white blood cell [WBC] differential) by 100 and then multiplying the quotient obtained by the total number of WBCs.

The degree or severity of neutropenia, rate of neutrophil decline, and duration of neutropenia are important risk factors for infection.[1–5] All patients with neutropenia are considered to be at risk for infection, but those with ANC less than 500 cells/mm^3 (0.5 × 10^9/L) are at greater risk than those with ANCs of 500 to 1,000 cells/mm^3 (0.5 × 10^9 to 1.0 × 10^9/L). Most treatment guidelines use ANC less than 500 cells/mm^3 (0.5 × 10^9/L) as the critical value in making therapeutic decisions regarding the management of suspected or documented infections.[1–5] Risk of infection and death are greatest among patients with less than 100 neutrophils/mm^3 (0.1 × 10^9/L) ("profound neutropenia").[1–6] In patients with chemotherapy-induced neutropenia, the risk of infection is also increased according to both the rapidity of ANC decline and duration of neutropenia. Patients with severe neutropenia of more than 7 to 10 days' duration are considered to be at especially high risk for serious infections.[1–4] The duration of chemotherapy-induced neutropenia varies considerably among subsets of patients with cancer according to the specific chemotherapeutic agents used and the intensity of treatment. Patients undergoing HCT may have no detectable granulocytes in peripheral blood for up to 3 to 4 weeks and are at particular risk for severe infections with a variety of pathogens.[4–8]

Bacteria and fungi commonly cause infections in patients with neutropenia. Gram-negative bacilli (*Escherichia coli*, *Klebsiella pneumoniae*, *P. aeruginosa*) historically were the most common causes of bacterial infection and remain frequent pathogens.[3,5,7–12] During the 1980s gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis,* and other coagulase-negative staphylococci, streptococci, and enterococci) emerged as the most common cause of acute bacterial infections among patients with neutropenia, accounting for up to 80% of all bloodstream infections.[5] This shift was likely due to widespread use of prophylaxis with fluoroquinolones, aggressive chemotherapy regimens associated with severe mucositis, and more frequent use of central venous catheters.[5,7,9,10,13] However, gram-negative infections are again increasing in incidence and now account for approximately half of all bacterial infections.[4–7,10–12] Gram-negative infections are associated with significant morbidity and mortality, in large part due to increasing antibiotic resistance.[10–12] Patients who are neutropenic for extended periods and who receive broad-spectrum antibiotics are at high risk for fungal infections, usually due to *Candida* or *Aspergillus* spp.[1–7,13] Viral infections, although not as common as bacterial and fungal infections, also may cause severe infection in patients with neutropenia.[1,4,6,7] Successful treatment of infections in patients with neutropenia is highly dependent on resolution of neutropenia.[1–6,8]

Immune System Defects

Although not as readily quantifiable, abnormalities may exist in granulocyte function as well as in cell numbers. In addition to neutropenia, defects in T-lymphocyte and macrophage function (cell-mediated immunity), B-cell function (humoral immunity), or both predispose patients to infection.[3–5,7] Cellular immune dysfunction is the result of underlying disease or immunosuppressive drug therapy or radiation; these defects result in a reduced ability of the host to defend against intracellular pathogens. Patients with malignancies and transplant patients receiving a wide variety of immunosuppressive agents, such as cyclosporine, tacrolimus, sirolimus, mycophenolate, corticosteroids, azathioprine, antineoplastic agents, and chimeric antigen receptor T cell (CAR-T) therapy, are at risk for a wide variety of infections (Table 145-1). Although some of these pathogens are associated with only asymptomatic or mild disease in normal hosts, they may cause disseminated, life-threatening infections in immunocompromised hosts.

Underlying disease also frequently causes defects in humoral immune function. Patients with multiple myeloma and chronic lymphocytic leukemia have progressive hypogammaglobulinemia that results in defective humoral immunity. Splenectomy performed as a part of the staging process for Hodgkin's disease places patients at risk for infectious complications. Disease states with humoral immune dysfunction predispose the patient to serious, life-threatening infection with encapsulated organisms such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitidis*.

Destruction of Protective Barriers

Loss of protective barriers is a major factor predisposing immunocompromised patients to infection. Damage to skin and mucous membranes by surgery, venipuncture, IV and urinary catheters, radiation, and chemotherapy disrupts natural host defense systems, leaving patients at high risk for infection. Chemotherapy-induced mucositis may erode mucous membranes of the oropharynx and gastrointestinal (GI) tract and establish a portal for subsequent infection by bacteria, herpes simplex virus (HSV), and *Candida.*[1–6] Medical and surgical procedures, such as transplant surgery, indwelling IV catheter placement, bone marrow aspiration, biopsies, and endoscopy, further damage the integument and predispose patients to infection. Infections resulting from disruption of protective barriers usually are a result of skin flora, such as *S. aureus*, *S. epidermidis*, and streptococci.[3–5]

Environmental Contamination/Alteration of Microbial Flora

Infections in immunocompromised patients are caused by organisms either colonizing the host or acquired from the environment. Microorganisms may be easily transferred from patient to patient on the hands of hospital personnel unless strict infection prevention policies are followed. Contaminated equipment, such as nebulizers or ventilators, and contaminated water supplies have been responsible for outbreaks of *P. aeruginosa* and *Legionella pneumophila* infections, respectively. Foods, such as fruits and green leafy vegetables, which often are colonized with gram-negative bacteria and fungi, are sources of microbial contamination in immunocompromised hosts.[1,6]

Most infections in patients with cancer are caused by organisms colonizing body sites, such as the skin, oropharynx, and GI tract, and are therefore caused by the patient's own endogenous flora.[4–7] The GI tract is a common site from which infections in immunocompromised hosts originate. Periodontitis, pharyngitis, esophagitis, colitis, perirectal cellulitis, and bacteremias are caused predominantly by normal flora of the gut; bloodstream infections are thought to arise from microbial translocation across injured GI mucosa.[1,6,7] Normal flora may be significantly disrupted and altered; oropharyngeal flora rapidly change to primarily gram-negative bacilli in hospitalized patients. Many patients with cancer may already be colonized with gram-negative bacilli on admission as a result of frequent prior hospitalizations and clinic visits. In hospitalized patients with cancer, however, many infections are caused by colonizing organisms acquired after admission.[1]

Although hospitalization and severity of illness are important risk factors for colonization by gram-negative bacilli, administration of broad-spectrum antimicrobial agents has the greatest impact on flora of immunocompromised hosts. Use of these agents disrupts GI tract flora and predisposes patients to infection with more virulent or resistant pathogens. Antineoplastic drugs (eg, cyclophosphamide, doxorubicin, and fluorouracil) and acid-suppressive therapy (eg, H_2-receptor antagonists, proton-pump inhibitors, and antacids) also may result in changes in GI flora and possibly predispose patients to infection.[1,4,5]

ETIOLOGY OF INFECTIONS IN PATIENTS WITH NEUTROPENIA AND CANCER

② Infection remains a significant cause of morbidity and mortality in neutropenic patients with cancer. Febrile neutropenia occurs in 10% to 50% of patients with solid tumors and 80% to 100% of those with hematological malignancies.[1,2,5] More than 50% of patients with febrile neutropenia have an established or occult infection, but causative pathogens are microbiologically documented in only 30% to 40% of cases. Infections can be documented clinically (but not microbiologically) in another 30% to 40% of patients, with the remaining 20% to 40% of patients manifesting infection only by fever.[2–5] Bloodstream infections account for approximately 10% to 25% of all febrile episodes during neutropenia.[1,4,5,9] Patients with profound neutropenia are at greatest risk for systemic infection, with at least 20% of these individuals developing bacteremia.[1–6] Areas of impaired or damaged host defenses, such as the oropharynx, lungs, skin, sinuses, and GI tract, are common sites of infection. These local infections may progress to cause systemic infection and bacteremia.[4,5,8,9]

Table 145-1 lists organisms commonly infecting immunocompromised patients. Bacteremic episodes in patients with cancer are caused by gram-positive organisms in 45% to 75% of cases, these rates being highly institution specific.[1,3,5,7,9–11,13] Important risk factors for these infections include frequent use of indwelling central and peripheral IV catheters, frequent use of broad-spectrum antibiotics with excellent gram-negative activity but often relatively poor gram-positive coverage, high rates of mucositis caused by aggressive cancer treatments, and prophylaxis with trimethoprim–sulfamethoxazole or fluoroquinolones.[1,3,5,7–11,14] Staphylococci (especially *S. epidermidis*) account for most infections, but *Bacillus* spp. and *Corynebacterium jeikeium* are also important pathogens.[1,4,5,7,13] Rates of infection due to methicillin-resistant *S. aureus* (MRSA) have increased in the hospital and community settings.[4–6,13,14,16] Viridans streptococci, which may be resistant to β-lactams, also have emerged as important pathogens, particularly in patients with chemotherapy-induced mucositis of the oropharynx.[3–6,12] Enterococci, including vancomycin-resistant strains, also may be problematic in many institutions.[4,6,13,14,16] Bacteremia caused by vancomycin-resistant enterococci (VRE) in patients with neutropenia is associated with a mortality rate up to 30%.[3,10,13,14,16,17]

Gram-positive infections are not always immediately life-threatening and are associated with somewhat lower mortality rates overall (approximately 5%-10%) compared with gram-negative infections.[1,4,10] However, increasing rates of antibiotic resistance have made treatment of gram-positive infections in immunocompromised patients more challenging.[4,7,10,13,14] MRSA infections are associated with increased morbidity, mortality, and hospital costs compared with susceptible organisms.[10,13,18] Methicillin resistance among coagulase-negative staphylococci, which may cause 40% to 80% of infections in certain populations, is common (70%-90% of isolates).[1,4,6,7,10,13,14] Vancomycin-resistant organisms such as VRE are increasing in importance.[1,3,4,10,13,17] Thus, prevention and timely diagnosis and treatment of gram-positive infections are clearly of great importance in the management of patients with neutropenia and cancer.

Gram-negative infections remain important causes of morbidity and mortality (approximately 10%-30%) in immunocompromised patients with cancer.[5,10] However, the relative frequency of gram-negative infections caused by specific pathogens has been changing. *E. coli* and *Klebsiella* remain the most common isolates at many centers.[4,5,7] However, strains of Enterobacterales producing extended-spectrum β-lactamases (ESBLs) that hydrolyze cephalosporins, and carbapenemases that inactivate carbapenems, have emerged and are a cause for concern.[1,4,5,7,10,14] The global spread of carbapenem-resistant enterobacterales (CRE) is especially concerning. The frequency of infections resulting from other gram-negative organisms, such as *Klebsiella-Enterobacter*, *Serratia*, and *Citrobacter*, has also been increasing.[1,4,5] Infections with these particular organisms may be difficult to treat because of the ease of β-lactamase induction and the more frequent development of resistance to multiple antibiotics.[1,4,5,7,10–12,14]

P. aeruginosa has long been an important pathogen in patients with cancer. *P. aeruginosa* infection rates are decreasing in patients with solid tumors but not in patients with hematologic malignancies.[3,7,10] Infections caused by *P. aeruginosa* are associated with significant morbidity and mortality in patients with neutropenia, with reported mortality rates of 31% to 75%.[1,5,10] The frequency of infection caused by difficult-to-treat organisms such as *Stenotrophomonas maltophilia* appears to be increasing at many centers, probably because of selective pressures of broad-spectrum antimicrobial use.[7,11] As with gram-positive organisms, antibiotic resistance among gram-negative organisms has continued to increase at alarming rates and has made appropriate antibiotic selection for treatment of febrile neutropenia more difficult.[1,5,14,16] Mortality rates of up to 40% to 70% have been reported in patients with infection caused by multidrug-resistant gram-negative pathogens.[5,14] Although the GI tract is a common site of bacterial infection, severe infections caused by anaerobic organisms are relatively infrequent. Anaerobes are found most frequently in mixed infections, such as perirectal cellulitis and mucositis-associated oropharyngeal infections.[4,7]

In addition to bacterial infections, neutropenic cancer patients are at risk for invasive fungal infections. Patients with extended periods of profound neutropenia who have been receiving broad-spectrum antibiotics, corticosteroids, or both are at the highest risk for invasive fungal infection. Up to one-third of patients with febrile neutropenia who do not respond to 1 week of broad-spectrum antibiotic therapy will have a systemic fungal infection.[1,4,11] Large autopsy studies have documented a change over time in invasive fungal infections. Whereas from 1989 to 2003 over 30% of autopsies of patients with hematologic malignancies found deep fungal infection (75% of which were undiagnosed prior to death), this number decreased to 19% from 2004 to 2008 (49% undiagnosed prior to death). These improvements may be due to improved awareness, diagnostic techniques, and treatments. One single center estimated the average prevalence of invasive fungal infections was 30% in those autopsied over a 20-year period. Causative pathogens were usually either *Aspergillus* spp., *Candida* spp., or Mucorales fungi (such as *Mucor* spp.).[16] Mortality rates in patients with invasive fungal infections are highly dependent on pathogens, sites of infection, and underlying risk factors but often exceed 30% overall.[17]

Candida albicans is a common fungal pathogen in neutropenic cancer patients, especially those with solid tumors.[1,3,4,15,19,21] However, non-*albicans* species of *Candida* including *Candida glabrata*, *C. tropicalis*, *C. parapsilosis*, and *C. krusei* are being isolated with increasing frequency and are more common than *C. albicans* infections in some studies.[15,21] Increased infections caused by pathogens such as *Trichosporon* spp., *Fusarium* spp., and *Curvularia* spp. have also been reported.[15,19,22] The shift toward more frequent infection with non-*albicans Candida* is important because of significantly decreased rates of azole susceptibility among many of these strains.[19] Because *Candida* spp. are normal flora, alteration of body host defenses is an important risk factor for the development of these infections. Oral thrush is the most common clinical manifestation of fungal infection. Mucous membranes damaged from chemotherapy and radiation serve as areas of *Candida* surface colonization and subsequent entry into the bloodstream; disease then may disseminate throughout the body. Organs such as the liver, spleen, kidney, and lungs are commonly involved in disseminated disease.[1,4,19] Hepatosplenic candidiasis is a particularly important infection in patients with hematologic malignancies.[7,19,21] In patients with invasive candidiasis, overall attributable mortality is as high as 35% to 50%.[3,13,15,18,21]

Invasive infections caused by *Aspergillus* spp. are a serious complication of neutropenia. Mortality rates have historically approached 80% in patients with prolonged neutropenia and/or patients undergoing allogeneic HCT; however, mortality is now reported as low as 30%.[3,20,22,24] These infections are particularly prevalent and more common in patients with hematologic malignancies and in patients undergoing HCT; invasive aspergillosis may occur in up to 10% of these patients.[3,15,19,22,24,25] Infections resulting from *Aspergillus* species (including *A. fumigatus*, *A. terreus*, *A. flavus*, and *A. niger*) usually are acquired via inhalation of airborne spores. After colonizing the lungs, *Aspergillus* invades the lung parenchyma and pulmonary vessels, resulting in hemorrhage, pulmonary infarcts, and a high mortality rate. Invasive pulmonary disease is the dominant manifestation of infection in patients with neutropenia. However, *Aspergillus* also may cause other infections, including sinusitis, cutaneous infection, and disseminated disease involving multiple organs, including the CNS.[19,25] Prolonged neutropenia is the primary risk factor for invasive pulmonary aspergillosis in patients with acute leukemia; use of corticosteroids also may predispose patients to disease.[21] Invasive aspergillosis should be suspected in neutropenic cancer patients colonized with *Aspergillus* (in sputum and/or nasal cultures) who remain persistently febrile despite at least 1 week of broad-spectrum antibiotic therapy.[1,4,25] Increased infections caused by other yeasts (such as *Trichosporon*) and molds (such as Mucorales, *Fusarium*, and *Curvularia*) have also been reported.[13,15,16,19,22]

Chemotherapy-induced mucous membrane damage may predispose neutropenic cancer patients to reactivation of HSV, manifesting as gingivostomatitis or recurrent genital infections. Untreated oropharyngeal HSV infections may spread to involve the esophagus and often coexist with *Candida* infections. Clinical disease resulting from HSV occurs most often in patients with serologic evidence (eg, serum antibodies to HSV) of prior infection. Both HSV-seropositive HCT recipients and HSV-seropositive patients with leukemia receiving intensive chemotherapy are at high risk for recurrent HSV disease during periods of immunosuppression.[3,4,6]

Pneumocystis jirovecii and *Toxoplasma gondii* are the most common parasitic pathogens found in immunocompromised cancer patients. Patients with hematologic malignancies and those receiving high-dose corticosteroids as part of chemotherapy regimens are at the greatest risk of infection.[3,4,6] Routine use of trimethoprim–sulfamethoxazole prophylaxis has substantially reduced the incidence of these infections.[1,4,6]

Because the majority of infecting organisms in patients with cancer are from the host's own flora, some centers have used routine surveillance cultures in an attempt to prospectively identify causes of fever and suspected infection. In a typical surveillance culture program, cultures of the nose, mouth, axillae, and perirectal area are performed twice weekly, and culture results are correlated with the clinical status of the patient. Because these cultures are costly and have low diagnostic yield, the utility of surveillance culture programs is believed to be limited.[1,4] However, surveillance cultures are useful as research tools and in patients with prolonged profound neutropenia, and in institutions that have high rates of antimicrobial resistance or have problems with pathogens such as *P. aeruginosa* or *Aspergillus* spp. Surveillance cultures should be limited to the anterior nares for detecting colonization with MRSA, *Aspergillus*, and penicillin-resistant pneumococci and to the rectum for detecting VRE, *P. aeruginosa*, and multiple-antibiotic-resistant gram-negative bacilli (such as CRE).[1,4]

Knowledge of infection rates and local susceptibility patterns is essential for guiding optimal management of febrile neutropenia. These parameters must be monitored closely because the spectrum of infectious complications is related to multiple factors, including cancer chemotherapy regimens and antimicrobial therapy used for treatment and prophylaxis.

CLINICAL PRESENTATION

4 The most important clinical finding in the patient with neutropenia is fever. Because of the potential for significant morbidity and mortality associated with infection in these patients, fever should be considered to be the result of infection until proved otherwise.[1,2,4,5,7] At the first appearance of fever, the patient should be evaluated carefully for other signs and symptoms of infection. The use of biomarkers such as procalcitonin (PCT) has been extensively investigated for their utility in helping diagnose infections in patients with febrile neutropenia. Although elevated PCT levels (typically ≥0.5 ng/mL [mcg/L]) have been associated with a significantly greater likelihood of bacterial infection in the febrile patient, lack of elevated PCT levels does not necessarily correspond to lack of infection and should not be used as the sole rationale for withholding or stopping initial antibiotic therapy.[22]

CLINICAL PRESENTATION: Febrile Neutropenia[1–7]

General

- Due to high risk for serious infections, frequent (at least daily) careful clinical assessments must be performed to search for possible evidence of infection
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites

Symptoms

- Usual signs and symptoms of infection may be absent or altered in patients with neutropenia owing to low numbers of leukocytes and an inability to mount an inflammatory response (eg, no infiltrate on chest x-ray film, urinary tract infection without pyuria)
- Pain may be present at the infection site(s)

Signs

- Fever in this setting is defined as a single oral temperature ≥38.3°C (100.9°F) in the absence of other causes or temperature ≥38°C (100.4°F) for 1 hour or more. Other causes of fever unrelated to infection in this patient population include reactions to blood products, chemotherapeutic agents (and other drugs, including biologics), cell lysis, and underlying malignancy
- Usual signs of infection may be absent or altered; patients with bacteremia commonly exhibit no signs of infection other than fever

Laboratory Tests

- Neutropenia (ANC ≤1,000 cells/mm^3 [1.0×10^9/L])
- Blood cultures (two or more sets, including vascular access devices) for bacteria and fungi; cultures of other suspected infection sites (infection can be documented microbiologically in only about 30% of cases, about half of which are due to bacteremia)
- Other cultures should be obtained as indicated clinically according to the presence of signs or symptoms
- Recent surveillance cultures (nasal, rectal) should be reviewed, if available
- Complete blood count and blood chemistries should be obtained frequently to monitor neutropenia, plan supportive care, guide drug dosing, and assess patient’s overall status

Other Diagnostic Tests

- Chest x-ray film
- Aspiration, biopsy of skin lesions
- Procalcitonin is indicative of bacterial infection when elevated, but negative test does not rule out infection
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

TREATMENT

Management of patients with febrile neutropenia, including both prophylaxis and treatment of infectious complications, can be extremely challenging. Although published guidelines are available, the most optimal clinical management of these patients remains unclear in many aspects.

Desired Outcomes

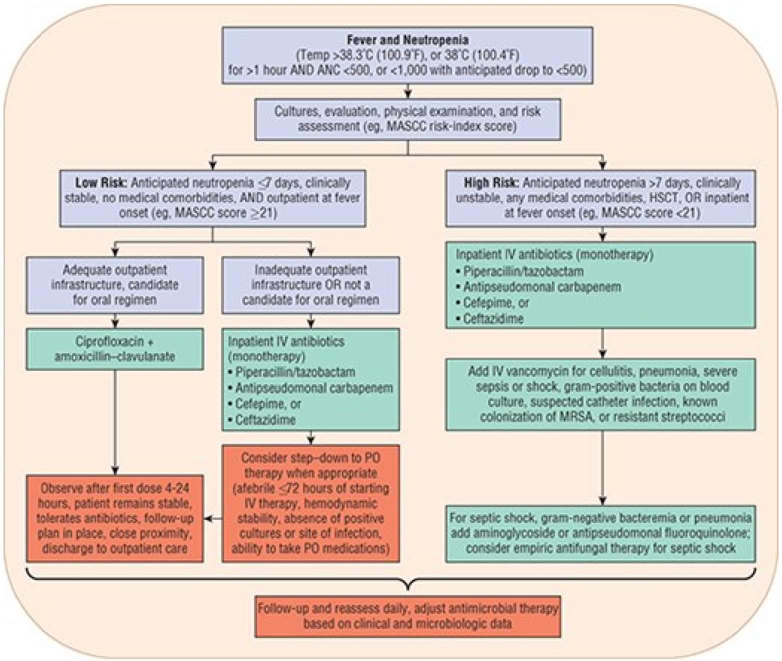
④ ⑤ The goals of therapy in neutropenic cancer patients with new fever are the following: (a) protect the neutropenic patient from early death caused by undiagnosed infection; (b) prevent breakthrough bacterial, fungal, viral, and protozoal infections during periods of neutropenia; (c) effectively treat established infections; (d) reduce morbidity and allow for continued administration of optimal antineoplastic therapy; (e) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (f) minimize toxicities and cost of antimicrobial therapy while increasing patient quality of life. Empirical broad-spectrum antibiotic therapy is effective at reducing early mortality.[1,2,4,9,10]

Approach to Treatment

General guidelines for management of febrile episodes and documented infections in patients with neutropenia are shown in Figs. 145-1 and 145-2.[1] Although many controversies remain regarding optimal management of these patients, updated evidence-based guidelines from the Infectious Diseases Society of America (IDSA) for the management of febrile neutropenia were published in 2010 and, regarding outpatient management, in 2018.[1,2] Similarly, the National Comprehensive Cancer Network (NCCN) published updated clinical practice guidelines for the prevention and treatment of cancer-related infections in 2021.[4] Selected specific recommendations are discussed in the following sections of this chapter, and their associated evidence-based rankings are summarized in Table 145-2.

FIGURE 145-1

Initial management of febrile episodes in patients with neutropenia. (ANC, absolute neutrophil count [expressed as cells/mm^3]; HCT, hematopoietic stem cell transplantation; MASCC, Multinational Association for Supportive Care in Cancer; PO, oral)



Fever and Neutropenia
(Temp >38.3°C (100.9°F), or 38°C (100.4°F)
for >1 hour AND ANC <500, or <1,000 with anticipated drop to <500)
Cultures, evaluation, physical examination, and risk assessment (eg, MASCC risk-index score)
Low Risk: Anticipated neutropenia ≤7 days, clinically stable, no medical comorbidities, AND outpatient at fever onset (eg, MASCC score ≥21)
High Risk: Anticipated neutropenia >7 days, clinically unstable, any medical comorbidities, HSCT, OR inpatient at fever onset (eg, MASCC score <21)
Adequate outpatient infrastructure, candidate for oral regimen
Inadequate outpatient infrastructure OR not a candidate for oral regimen
Inpatient IV antibiotics (monotherapy)
• Piperacillin/tazobactam
• Antipseudomonal carbapenem
• Cefepime, or
• Ceftazidime
Ciprofloxacin + amoxicillin–clavulanate
Inpatient IV antibiotics (monotherapy)
• Piperacillin/tazobactam
• Antipseudomonal carbapenem
• Cefepime, or
• Ceftazidime
Add IV vancomycin for cellulitis, pneumonia, severe sepsis or shock, gram-positive bacteria on blood culture, suspected catheter infection, known colonization of MRSA, or resistant streptococci
Consider step–down to PO therapy when appropriate (afebrile ≤72 hours of starting IV therapy, hemodynamic stability, absence of positive cultures or site of infection, ability to take PO medications)
Observe after first dose 4-24 hours, patient remains stable, tolerates antibiotics, follow-up plan in place, close proximity, discharge to outpatient care
For septic shock, gram-negative bacteremia or pneumonia add aminoglycoside or antipseudomonal fluoroquinolone; consider empiric antifungal therapy for septic shock
Follow-up and reassess daily, adjust antimicrobial therapy based on clinical and microbiologic data

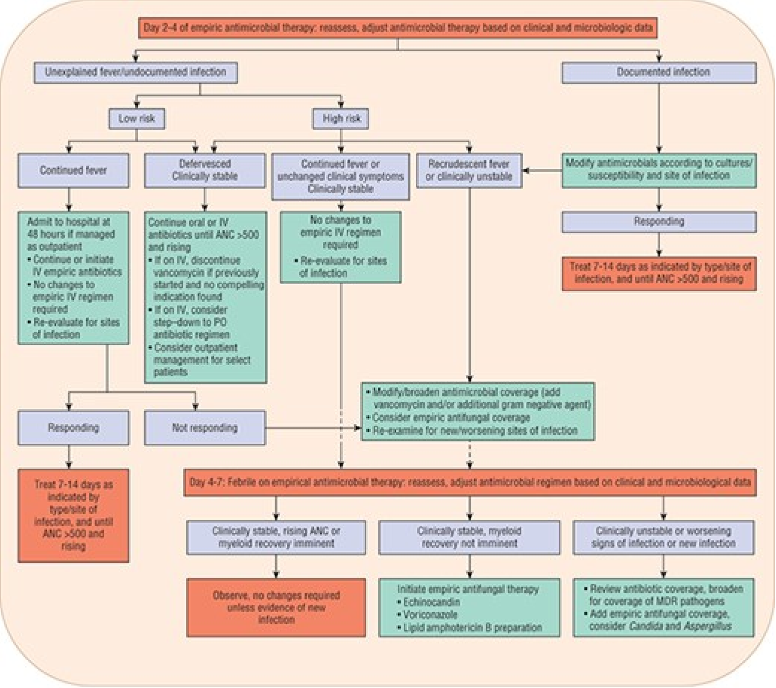
FIGURE 145-2

Subsequent management of febrile episodes in patients with neutropenia who have already received empirical antimicrobial therapy for 2 to 4 days. (ANC, absolute neutrophil count [expressed as cells/mm^3 or x 10^6/L; MDR, multidrug-resistant; PO, oral)



Day 2-4 of empiric antimicrobial therapy: reassess, adjust antimicrobial therapy based on clinical and microbiologic data
Unexplained fever/undocumented infection
Documented infection
Low risk
High risk
Continued fever
Defervesced Clinically stable
Continued fever or unchanged clinical symptoms Clinically stable
Recrudescent fever or clinically unstable
Modify antimicrobials according to cultures/susceptibility and site of infection
Admit to hospital at 48 hours if managed as outpatient
• Continue or initiate IV empiric antibiotics
• No changes to empiric IV regimen required
• Re-evaluate for sites of infection
Continue oral or IV antibiotics until ANC >500 and rising
• If on IV, discontinue vancomycin if previously started and no compelling indication found
• If on IV, consider step-down to PO antibiotic regimen
• Consider outpatient management for select patients
No changes to empiric IV regimen required
• Re-evaluate for sites of infection
Responding
Treat 7-14 days as indicated by type/site of infection, and until ANC >500 and rising
• Modify/broaden antimicrobial coverage (add vancomycin and/or additional gram negative agent)
• Consider empiric antifungal coverage
• Re-examine for new/worsening sites of infection
Responding
Not responding
Treat 7-14 days as indicated by type/site of infection, and until ANC >500 and rising
Day 4-7: Febrile on empirical antimicrobial therapy: reassess, adjust antimicrobial regimen based on clinical and microbiological data
Clinically stable, rising ANC or myeloid recovery imminent
Clinically stable, myeloid recovery not imminent
Clinically unstable or worsening signs of infection or new infection
Observe, no changes required unless evidence of new infection
Initiate empiric antifungal therapy
• Echinocandin
• Voriconazole
• Lipid amphotericin B preparation
• Review antibiotic coverage, broaden for coverage of MDR pathogens
• Add empiric antifungal coverage, consider Candida and Aspergillus

TABLE 145-2

Summary of Evidence-Based Recommendations for Management of Febrile Episodes in Patients with Neutropenia

Recommendations	Recommendation Grades[a]
The first dose of empirical antibiotic therapy should be administered within 1 hour after triage from initial presentation	Strong, low
Oral antibiotics are feasible for treatment of carefully selected patients at low risk for complications	A-1
Clinical judgment and consideration of multiple patient factors should be used when selecting candidates for outpatient management	Moderate, low
The MASCC index, Talcott's rules, and CISNE are recommended tools for identifying patients who may be candidates for outpatient management	Moderate, intermediate
Patients who are eligible for outpatient management must meet appropriate psychosocial and logistical requirements	Moderate, low
For outpatient management, first doses of antibiotics should be administered in the clinic, emergency department, or hospital	Moderate, low
Monotherapy with appropriate antibiotics is as effective as combination regimens for initial empirical treatment of febrile neutropenic episodes	A-1
Patients at high risk for serious life-threatening infections must be initially treated with IV antibiotics. Patients at low risk can be treated with either IV or oral drugs (see text for risk stratification criteria)	A-2
Oral therapy with a fluoroquinolone (ciprofloxacin or levofloxacin) plus amoxicillin-clavulanate is appropriate for initial outpatient treatment	Moderate, intermediate

Patients who become afebrile within 2-4 days of beginning initial empirical antibiotic therapy and in whom specific organisms have been identified should be treated for ≥7 days (until cultures are negative and patient has clinically recovered). Low-risk patients in whom no organism is identified can be switched to oral antibiotics if desired, whereas patients originally classified as high risk should continue on IV antibiotics	B-2
Management of Patients with Persistent Fever During First 2-4 Days of Treatment	
In patients initially receiving monotherapy or a two-drug regimen *not* including vancomycin, addition of vancomycin can be considered if any criteria for use of vancomycin are present (see the text for specific criteria)	B-3
In patients *already* receiving vancomycin as part of the initial empirical regimen, withdrawal of vancomycin should be considered after 2 days in the absence of a documented pathogen requiring continued therapy	A-2
Other initial antibiotics can be continued if the disease has not progressed, or switched to oral therapy if the patient was classified as low risk even in the presence of continued fever	A-1
Management of Patients with Fever Persisting for More Than 2-4 Days After Initial Treatment	
Reassess patient after 2 days of treatment. If still febrile by day 4, then: (a) continue the same antibiotics if clinically stable; (b) change antibiotics if any evidence of disease progression or antibiotic toxicities; or (c) add an antifungal drug if the duration of neutropenia is expected to be more than 5-7 additional days	Option a: A-1 Option b: A-3 Option c: A-3
Continuation of Antibiotics in Afebrile Patients with no Identified Infection	
Antibiotic therapy can be discontinued after 3 days of treatment if patient is afebrile for ≥48 hours and absolute neutrophil count (ANC) is ≥500 cells/mm^3 (0.5 × 10^9/L) for 2 consecutive days	A-2
If patient remains neutropenic, continue IV or oral antibiotics	A-2
Antibiotics should be continued in patients with profound neutropenia (ANC <100 cells/mm^3 [0.1 × 10^9/L]), mucous membrane lesions of mouth or GI tract, unstable vital signs, or other identified risk factors	A-2
Antibiotics can be stopped after 2 weeks in patients with prolonged neutropenia of unclear continued duration, no identified site of infection, and who can be closely observed	C-3
Alternatively, antibiotics can be discontinued after 4 days if no infection is documented and the patient shows no response to therapy	C-3
Management of Fungal Infections	
Suspected candidiasis:	
Lipid-associated amphotericin B (LAMB) or caspofungin[b]	A-1
Voriconazole	B-1
Fluconazole or itraconazole	B-1
Candidemia:	
An echinocandin[b] or LAMB	A-2

Fluconazole or voriconazole	B-3
Granulocyte Transfusions	
There are no specific indications for routine use of granulocyte transfusions	C-2
Colony-Stimulating Factors	
Colony-stimulating factors are not indicated for routine treatment of neutropenia in either febrile or afebrile patients	B-2
Prophylactic use of colony-stimulating factors should be considered for patients in whom the anticipated risk of fever and neutropenia is ≥20%	A-2
Antimicrobial Prophylaxis in Patients with Neutropenia	
Fluoroquinolone prophylaxis should be considered for high-risk patients with profound neutropenia (ANC <100 cells/mm^3 [0.1×10^9/L]) expected to last 7-10 days	Moderate, high
Antibacterial prophylaxis is not required in routinely recommended in low-risk patients who are expected to be neutropenic <7 days	A-3
Prophylaxis with trimethoprim–sulfamethoxazole should be administered to all patients at high risk for *Pneumocystis jirovecii* pneumonia, regardless of whether they are neutropenic	Strong, high
Prophylaxis with an oral triazole or parenteral echinocandin is recommended in high-risk patients, starting with induction chemotherapy and continued for duration of neutropenia	Moderate, intermediate
In HCT, prophylaxis with fluconazole, micafungin[b], posaconazole, itraconazole, voriconazole, or LAMB is recommended during the period of risk of neutropenia	A-1 for fluconazole and micafungin[b], all others B-2
In HCT recipients with graft-versus-host disease, or patients with neutropenia with hematologic malignancies, prophylaxis with posaconazole is recommended for prevention of invasive fungal infections	A-1
HSV-seropositive patients undergoing HCT or leukemia induction therapy should receive acyclovir prophylaxis during neutropenia, and for at least 30 days after HCT	Strong-high for prophylaxis, A-2 for duration
In HCT, prophylaxis with acyclovir should be administered during neutropenia and for at least 1 year afterward to prevent VZV infection or reactivation	A-2

[a] Cited evidence-based guidelines utilize different systems for grading the strengths of recommendation and quality of the associated evidence. Letter/number-based recommendations are from references 1 and 2; qualitative (descriptive) recommendations are from the other cited guidelines. Readers are advised to consult the original documents for full explanations of the grading systems and definitions used in individual guidelines.

[b] Expert opinion indicates all echinocandins are likely interchangeable and equally effective.

Strength of recommendations: A, B, C = good, moderate, and poor evidence to support recommendation for use, respectively; D = moderate evidence to support a recommendation against use. *Quality of evidence*: 1 = evidence from ≥1 properly randomized, controlled trial; 2 = evidence from ≥1 well-designed clinical trial without randomization, from cohort or case–control analytic studies, from multiple time series, or from dramatic results from uncontrolled experiments; 3 = evidence from opinions of respected authorities, based on clinical experience, descriptive studies, or reports of expert committees.

Qualitative (descriptive) recommendations: *Strong, high*: strong recommendation based on high-quality evidence; *Strong, moderate*: strong recommendation based on moderate-quality evidence; *Strong, low*: strong recommendation based on low-quality evidence; *Moderate, high*: moderate recommendation based on high-quality evidence; *Moderate, intermediate*: moderate recommendation based on intermediate-quality evidence; *Moderate, low*: moderate recommendation based on low-quality evidence; *Weak, moderate*: weak recommendation, moderate quality evidence from RCTs with important limitations or exceptionally strong evidence from unbiased observational studies; *Weak, low*: weak recommendation, low-quality evidence for at least one critical outcome from observational studies, RCTs with serious flaws, or indirect evidence.

Data from references 1,2,4,6,22,23,25.

Fever in the neutropenic cancer patient is considered to be caused by infection until proved otherwise. High-dose broad-spectrum bactericidal, usually parenteral, empirical antibiotic therapy should be initiated at the onset of fever or at the first signs or symptoms of infection. Withholding antibiotic therapy until an organism is isolated results in unacceptably high mortality rates. Undiagnosed infection in immunocompromised patients can rapidly disseminate and result in death if left untreated or if treated improperly. For example, failure to initiate appropriate antibiotic therapy for *P. aeruginosa* bacteremia at the onset of fever in neutropenic cancer patients resulted in mortality rates of 15%, 48%, and 70% within 12, 24, and 48 hours, respectively.[1,4,27] Appropriate empirical antibiotic therapy is 70% to 90% effective at reducing early morbidity and mortality.[1,4,10] Therapy must be appropriate and initiated promptly, ideally within 1 hour after initial onset of fever. Antimicrobial therapy must likewise be initiated promptly in neutropenic patients with cancer who are afebrile but with other clinical signs and symptoms of possible infection.

When designing optimal empirical antibiotic regimens, clinicians must consider infection patterns and antimicrobial susceptibility trends in their respective institutions. Patient factors such as risk for infection, drug allergies, concomitant nephrotoxins, and previous antimicrobial exposure (including prophylaxis) must be considered.[1–4] Assessment of the patient's risk of infection will help determine the appropriate route and setting (eg, inpatient versus outpatient) for antibiotic administration (Fig. 145-1). Patients with neutropenia and fever can be divided into low- and high-risk groups for complications of severe infection. Risk stratification drives both type and setting of antimicrobial therapy. The Multinational Association for Supportive Care in Cancer (MASCC) risk-index score is recommended by many clinical guidelines to assess a patient's risk of complications.[1,2,4] Additional evaluation tools including Talcott groups and the Clinical Index of Stable Febrile Neutropenia (CISNE) score are also recommended.[2] These tools are provided in Table 145-3.

TABLE 145-3

Tools for Evaluating Febrile Neutropenia and Identifying Low-Risk Individuals for Outpatient Management

	Patient Characteristic	Score or Group
MASCC		
	Burden of febrile neutropenia: no or mild symptoms *OR* moderate symptoms	5 points
		3 points
	No hypotension (systolic blood pressure >90 mmHg	5 points
	No chronic obstructive pulmonary disease	4 points
	Solid tumor or hematologic malignancy with no previous fungal infection	4 points
	No dehydration requiring parenteral fluids	3 points
	Outpatient status	3 points
	Age <60 years	2 points
Maximum total score = 26 points; score ≥21 points indicates low risk for medical complications		
Talcott		
	Inpatients at time of fever onset	Group I
	Outpatients with acute comorbidity requiring, by itself, hospitalization	Group II
	Outpatients without comorbidity but with uncontrolled cancer	Group III
	Outpatients with cancer controlled and without comorbidity	Group IV
Groups I-III = high risk; Group IV = low risk		
CISNE		
	Eastern Cooperative Oncology Group performance status ≥2	2 points
	Stress-induced hyperglycemia	2 points
	Chronic obstructive pulmonary disease	1 point
	Chronic cardiovascular disease	1 point
	National Cancer Institute Common Toxicity Criteria mucositis of grade ≥2	1 point
	Monocytes <200/μL (0.2 x 10^9/L)	1 point

Maximum total score = 8 points; 0 points = low risk; 1-2 points = intermediate risk; ≥3 points = high risk. Suggested for use with patients with solid tumors who have undergone mild-to-moderate intensity chemotherapy and who appear to be clinically stable. Patients with CISNE score 0-2 would be considered candidates for outpatient management.

Data from References 2,4.

Most experts agree that, in general, low-risk patients have an anticipated duration of neutropenia less than or equal to 7 days, are clinically stable, and have no or few comorbidities, and have no bacterial focus or systemic signs of infection other than fever. In contrast, high-risk patients are those with an anticipated duration of neutropenia greater than 7 days or profound neutropenia, are clinically unstable or have comorbid medical problems (eg, focal or systemic signs of infection, GI symptoms, nausea, vomiting, diarrhea, hypoxemia, and chronic lung disease), or have a high-risk cancer (eg, acute leukemia) and/or have undergone high intensity chemotherapy. High-risk patients (eg, MASCC less than 21, Talcott Groups I through III, CISNE ≥ 3) should be hospitalized for parenteral antibiotics whereas low-risk patients may be candidates for oral or outpatient antibiotics. Scoring tools such as MASCC must be used in conjunction with, not as a replacement for, careful clinical assessment of patients when selecting low-risk patients for oral outpatient management. Many additional patient factors (eg, worsening renal function, altered mental status, severe anemia, or thrombocytopenia) may increase risk of complications and potentially exclude patients from outpatient management of febrile neutropenia (see also "Oral Antibiotic Therapy for Management of Febrile Neutropenia" section below).[1,2,4,28]

The optimal antibiotic regimen for empirical therapy in febrile neutropenia remains controversial, but it is clear that no single regimen can be recommended for all patients. Because of their frequency and relative pathogenicity, *P. aeruginosa* and other gram-negative bacilli and staphylococci remain the primary targets of empirical antimicrobial therapy.[1,2,4] Although *P. aeruginosa* may be documented in fewer than 5% of bloodstream infections in the population of hospitalized patients, adequate antipseudomonal antibiotic coverage still must be included in empirical regimens because of the significant morbidity and mortality associated with this pathogen.[1,3,16] All empirical regimens must be carefully monitored and appropriately revised on the basis of documented infections, susceptibilities of bacterial isolates, development of more defined clinical signs and symptoms of infection, or a combination of these factors.

Although there are some differences among them, consensus guidelines generally recognize three different types of empirical parenteral antibiotic regimens: (a) monotherapy with an antipseudomonal β-lactam such as a cephalosporin (cefepime or ceftazidime), a carbapenem (imipenem–cilastatin or meropenem), or piperacillin–tazobactam; (b) two-drug combination therapy with an antipseudomonal β-lactam plus either an aminoglycoside or an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin); and (c) monotherapy or two-drug combination therapy as above, plus the addition of vancomycin (Fig. 145-1).[1,4] Each of these regimens has advantages and disadvantages, which are summarized in Table 145-4. There is no overwhelming evidence that any one of these regimens is superior to the others. The overall response to empirical antibiotic regimens in febrile neutropenic patients with cancer is approximately 70% to 90% regardless of whether a pathogen is isolated or which antimicrobial regimen is used.[1,3,4,10] Additionally, other alternative regimens may also be appropriate based on specific patient characteristics or susceptibilities of suspected pathogens within a specific institution.

TABLE 145-4

Comparative Advantages and Disadvantages of Various Antibiotic Regimens for Empiric Therapy of Febrile Neutropenic Patients with Cancer

Regimen	Potential Advantages	Potential Disadvantages
β-Lactam monotherapy (ceftazidime, cefepime, piperacillin–tazobactam, imipenem–cilastatin, or meropenem)	Efficacy comparable to combination regimens; decreased drug toxicities; ease of administration; possibly less expensive	Possibly less efficacy in profound neutropenia or prolonged neutropenia; limited gram-positive activity; no potential for additive/synergistic effects; increased selection of resistant organisms; increased colonization and superinfection rates
Antipseudomonal β-lactam plus aminoglycoside (eg, gentamicin or tobramycin + cefepime, ceftazidime, or piperacillin–tazobactam)	Traditional regimen, broad-spectrum coverage; optimal therapy of *Pseudomonas aeruginosa*; rapidly bactericidal; synergistic activity; decreased bacterial resistance; reduction of superinfections	Limited gram-positive activity; potential for nephrotoxicity; need for therapeutic monitoring of aminoglycoside concentrations
Antipseudomonal β-lactam plus fluoroquinolone (ciprofloxacin or higher-dose levofloxacin + ceftazidime, cefepime, or piperacillin–tazobactam)	Efficacy similar to other regimens when used in combination therapy; no cross-resistance with β-lactams; possibility for oral administration; may be useful in patients with renal impairment in whom aminoglycosides are undesirable	Marginal gram-positive activity; fluoroquinolones not recommended as monotherapy; resistance may develop rapidly
Empirical regimens containing vancomycin (added to antipseudomonal β-lactam ± aminoglycoside or fluoroquinolone)	Early effective therapy of gram-positive infections	No demonstrated benefit of vancomycin empirical therapy versus addition of vancomycin if needed later; increased risk of selection for vancomycin-resistant enterococci; risk of toxicities; excessive cost; need for therapeutic monitoring of vancomycin concentrations
Oral antibiotic regimens (eg, ciprofloxacin or levofloxacin + amoxicillin–clavulanate or clindamycin)	Efficacy comparable with parenteral therapy in low-risk patients; less expensive; reduced exposure of patients to nosocomial pathogens	Least studied treatment approach; less potent than parenteral antibiotics; requires compliant patient with 24-hour access to medical care should clinical instability develop

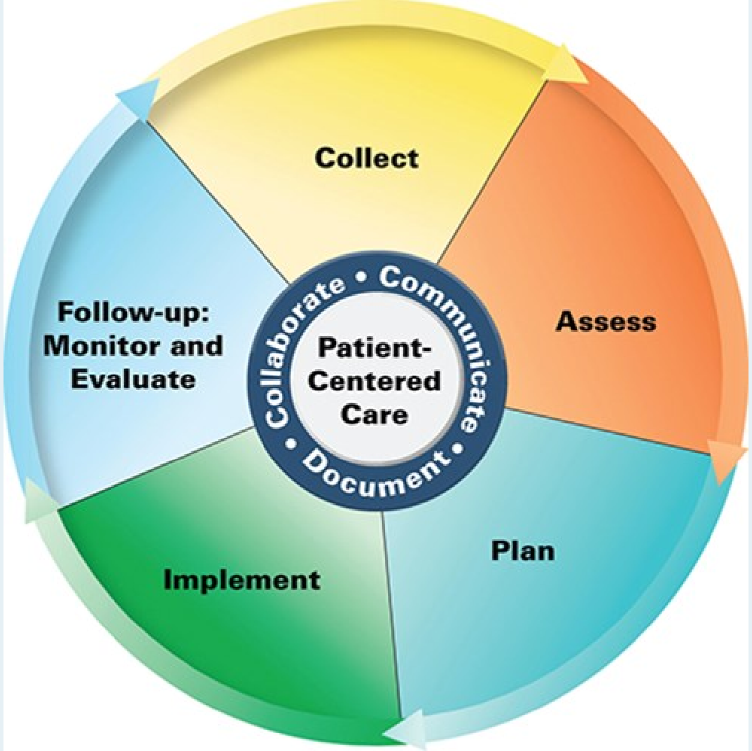
PATIENT CARE PROCESS

Patient Care Process for the Treatment of Suspected Infection in an Immunocompromised Host



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, height, weight)
- Patient medical history (oncologic, surgical, vaccines, previous infections, time since transplant/engraftment/last oncologic regimen or transplant engraftment)
- Social history (eg, drug/ethanol use), travel history (eg, endemic exposures)
- Current medications (eg, antimicrobial prophylaxis/treatment, immunomodulating agents [immunosuppressive or immunostimulatory])
- Prior medications (eg, antimicrobial, oncologic, immunomodulating) and future planned medications (eg, life-saving oncologic or immunomodulating regimens)
- Objective data

  Mean arterial blood pressure (MAP), heart rate (HR), respiratory rate (RR), O_2-saturation, altered mental status (AMS), urine output (UO), skin turgor/integrity

  Labs including white blood cells (WBC) with differential, absolute neutrophil count (ANC) and trends, serum creatinine (SCr), lactate, liver function tests (LFT), blood glucose

  Culture data (eg, bacterial, fungal, viral), microbiologic diagnostic tests (eg, procalcitonin, galactomannan, β-D-glucan, viral polymerase chain reaction tests, infectious serologies)

  Presence of central, peripheral, urinary catheters and indwelling ports

Assess

- For febrile neutropenia: assess risk of infectious complications for possible outpatient management (see Table 145-3) including logistical barriers (eg, access to care, compliance, support)

- Hemodynamic/clinical stability and evidence of organ malperfusion (eg, MAP <65 mmHg, HR >100 bpm, RR>22, AMS, decreased UO, renal dysfunction)
- Evidence of infection at common sites (see Clinical Presentation boxes: “Febrile Neutropenia” and “Infection in Solid Organ Transplant Patients”)
- Assess risk of infection based on duration/degree of neutropenia or magnitude of immunosuppression
- Assess need for colony-stimulating factors (CSF) (see Table 145-8)
- Assess risk for infection with specific pathogens (see Table 145-1)
- Assess contraindications to specific antimicrobial therapy (eg, allergies, drug-drug/disease interactions)
- Assess previous and current culture results and susceptibilities

Plan*

- Antimicrobial regimen including specific antimicrobial(s), dose, route, frequency, and duration (see Figs. 145-1, 145-2; Tables 145-4, 145-5, and 145-7)
- Monitoring parameters including efficacy (eg, resolution of infectious symptoms, fever, ANC) and safety (eg, antimicrobial side effects, *Clostridioides difficile*, CNS toxicity)
- Patient education if treated outpatient (eg, self-monitoring, when/how to seek help, adherence)
- Referrals to other providers when appropriate (eg, infectious disease specialist)

Implement*

- Provide patient and caregiver education regarding when/how to seek advance medical attention
- Provide integrated health professionals, patient and family education (eg, expected outcomes/goals of therapy, therapeutic drug monitoring, avoidance of exposures)

Follow-Up: Monitor and Evaluate*

- De-escalation of empiric antimicrobial regimens to targeted therapy (see Table 145-7)
- Resolution of infectious symptoms (see also Figs. 145-1 and 145-2)
- Presence of adverse effects specific to the antimicrobial regimen
- Presence of drug-drug interactions potentially requiring changes in drug regimens or additional therapeutic drug monitoring
- Patient adherence to outpatient antimicrobial plan
- Therapeutic drug levels to adjust antimicrobial therapy (see Table 145-6)

**Collaborate with patient, caregivers, and other healthcare professionals.*

β-Lactam Monotherapy

Monotherapy with an antipseudomonal β-lactam is recommended by IDSA 2010 and NCCN 2021 guidelines as initial parenteral therapy for management of febrile neutropenia without suspected or proven resistant organisms or complications (eg, pneumonia, hypotension, and vascular access infection).[1,4] β-Lactam antibiotics that have been evaluated as monotherapy for management of febrile episodes in neutropenic cancer patients, include antipseudomonal cephalosporins (ceftazidime and cefepime), piperacillin–tazobactam, and antipseudomonal carbapenems (imipenem–cilastatin and meropenem).[1,4] Three different meta-analyses assessing as many as 46 clinical trials involving more than 7,600 patients found no significant differences overall between monotherapy and combination therapy (β-lactam/aminoglycoside) in rates of survival, treatment response, and bacterial/fungal superinfections.[4,29] Monotherapy with antipseudomonal β-lactams is therefore recommended by treatment guidelines and routinely used for initial treatment.[1,4] Institutional susceptibility patterns and patient characteristics should drive drug selection for the management of individual patients with febrile neutropenia.[1,4]

Ceftazidime-avibactam, ceftolozane-tazobactam, and meropenem-vaborbactam, and cefiderocol have appropriate overall spectrum of antibacterial activity with good activity against *P. aeruginosa* and other gram-negative organisms as well as many gram-positive pathogens. Neither the 2021 NCCN nor the 2010 IDSA consensus guidelines specifically recommend these agents due to a lack of supportive clinical evidence at the time the guidelines were written.[1,4] These agents are also considered to be too broad-spectrum and expensive for routine empiric use. However, they may be considered reasonable treatment options in selected patients at high risk for, or with previous history of, infection with multidrug-resistant (MDR) pathogens or in institutions with high rates of infection with MDR pathogens in certain high-risk patients.

Use of monotherapy has several potential advantages and disadvantages (see Table 145-4). Perhaps the most common concerns are those regarding the selection of resistant strains of organisms, such as *P. aeruginosa*, *Klebsiella-Enterobacter* group, and *Serratia* spp., through expression of ESBL and type 1 β-lactamases, especially with ceftazidime.[1,4,10,14] Activity against gram-positive organisms such as coagulase-negative staphylococci, MRSA, enterococci (including VRE), penicillin-resistant *S. pneumoniae*, and some strains of viridans streptococci is poor with some single β-lactams, but cefepime and antipseudomonal carbapenems have good activity against most viridans streptococci and pneumococci.[1,4] Although ceftazidime has been widely studied and used for treatment of febrile neutropenia, newer agents may be more effective owing to ceftazidime's susceptibility to β-lactamase induction and lower activity against gram-positive organisms.[1,4,10,14,30] Ertapenem, a carbapenem, and ceftaroline, a cephalosporin active against MRSA, have excellent activity against many gram-negative organisms but should not be routinely used in the empirical treatment of febrile neutropenia due to their weak activity against *P. aeruginosa*. For the same reason, broad-spectrum tetracycline derivatives (eg, tigecycline, eravacycline, omadacycline) are not acceptable options for empiric monotherapy in most patients.

As with all empirical antibiotic regimens, patients receiving monotherapy should be monitored closely for treatment failure, secondary infections, and development of resistance. Use of monotherapy may not be appropriate in institutions with high rates of gram-positive infections or infections caused by relatively resistant gram-negative pathogens such as *P. aeruginosa* and *Klebsiella-Enterobacter*. The carbapenems are less susceptible to inducible β-lactamases and often may be used effectively in these institutions. Overall, similar efficacy has been observed with monotherapy with antipseudomonal β-lactams compared to aminoglycoside combination therapy for treatment of *P. aeruginosa* infections.[1,4,29]

Aminoglycoside Plus Antipseudomonal β-Lactam

Regimens consisting of an aminoglycoside plus an antipseudomonal β-lactam traditionally have been the most commonly used for empirical treatment of febrile neutropenia, although many such regimens may lack adequate gram-positive activity (see Table 145-4).[1,4] This relative lack of activity remains a concern because of the increasing frequency of gram-positive infections. The choice of aminoglycoside and β-lactam for inclusion in empirical regimens should be based on institutional epidemiology and antimicrobial susceptibility patterns. Similar efficacy is observed with an antipseudomonal β-lactam in combination with an aminoglycoside.[1,4,29]

Combinations of broad-spectrum β-lactams and aminoglycosides may provide improved activity (eg, synergy activity against bacteria commonly involved in neutropenic infections). The exact role of synergy in the outcome of patients with febrile neutropenia treated with empirical antibiotic therapy is somewhat controversial, particularly in light of the efficacy of single-drug regimens and nephrotoxicity associated with aminoglycosides.[29,30] Nevertheless, combinations of antibiotics appear to be beneficial in patients with persistent profound neutropenia.

Aminoglycoside toxicity may be a concern in patients receiving these regimens who are already receiving other nephrotoxic drugs, such as cisplatin and cyclosporine. Administration of aminoglycosides in large single daily doses (once-daily dosing) may be as effective, less costly, and no more toxic than conventional dosing methods. Although once-daily aminoglycoside dosing regimens appear to be safe and effective in these patients, standard dosing regimens are recommended for infections where data are not sufficient to recommend once-daily dosing (eg, endocarditis).[1,4]

Fluoroquinolones as a Component of Empirical Regimens

Because the fluoroquinolone antibiotics have broad-spectrum activity (particularly against gram-negative pathogens), rapid bactericidal activity, and favorable pharmacokinetic and toxicity profiles, these agents have been investigated as empirical therapy for febrile neutropenia. Ciprofloxacin is the preferred agent for use in this clinical setting because of its relatively better activity against *P. aeruginosa* and more extensive evidence-based support for its use.[1,4] Response rates to quinolone-containing combination regimens are comparable to those obtained with the other regimens described previously.[1,3,4] Ciprofloxacin is not recommended for monotherapy, however, because of its relatively poor activity against gram-positive pathogens, particularly streptococci, and variable response rates in clinical studies.[1,4] Although delafloxacin has a spectrum of antibacterial activity that seems favorable for febrile neutropenia, no data currently exist for this indication and its use is not recommended. Fluoroquinolones should also not be used as empirical therapy in patients who have received quinolones as infection prophylaxis because of the risk of drug resistance.[1,4] Rates of fluoroquinolone resistance are increasing, and streptococcal treatment failures are a concern.[12,14,16] Although fluoroquinolones are not generally considered first-line empirical therapy for inpatient use, they may be useful as one component of combination regimens in patients with allergies or other contraindications to first-line agents.[1,4]

Empirical Regimens Containing Vancomycin

The inclusion of vancomycin in initial empirical therapy of febrile neutropenic patients with cancer is not currently recommended by IDSA 2010 or NCCN 2021 guidelines unless the patient has specific risk factors; however, this remains an ongoing debate. This controversy continues because of the high incidence of gram-positive infections in this population, particularly MRSA. One approach is to include vancomycin in the initial empirical antibiotic regimen, thereby providing early effective treatment of possible gram-positive infections. Inclusion of vancomycin in initial empirical regimens may be appropriate because of higher rates of MRSA infections as well as aggressive chemotherapy regimens causing significant mucosal damage that increases the risk for streptococcal infections. Decreased mortality from penicillin-resistant viridans streptococcal infections has been observed when vancomycin was included in initial therapy.[1,6,30] A second approach is to withhold vancomycin from initial empirical regimens, later adding the drug if gram-positive organisms are isolated from cultures or if there is clinical deterioration. Support for both these approaches can be found in the medical literature.[1,4,30,31] Prospective studies and multiple meta-analyses have failed to document increased response rates or decreased mortality with the routine addition of vancomycin to initial empirical regimens, provided that vancomycin can be added later as needed.[1,4,30,31] In addition to increased costs of therapy, vancomycin was also associated with increased adverse effects, including nephrotoxicity.[4] Finally, concerns remain regarding selection of resistant gram-positive bacteria such as VRE with excessive vancomycin use.[1,4,26,32]

Vancomycin is recommended for inclusion in initial empirical regimens only in patients at high risk for gram-positive infection, particularly due to MRSA and coagulase-negative staphylococci (including patients with evidence of infection of central venous catheters and other indwelling lines), high risk for viridans streptococcal infection due to severe mucositis, or pneumonitis or soft tissue infection in hospitals with high rates of MRSA infections.[1,4,10,30] Rates of β-lactam resistance among viridans streptococci range up to 25%.[1,4] Empirical vancomycin use may be justified in institutions using empirical or prophylactic antibiotic regimens without good activity against streptococci (eg, ciprofloxacin) and in patients known to be colonized with MRSA or β-lactam–resistant pneumococci. In patients with preliminary culture results indicating gram-positive infection, empirical vancomycin is appropriate while the susceptibility results are pending. Lastly, empirical use of vancomycin may be recommended in patients with hypotension or other evidence of cardiovascular impairment or sepsis without an identified pathogen.[1,4] If empirical vancomycin therapy is initiated and no evidence of gram-positive infection is found after 48 to 72 hours, the drug should be discontinued.[1,4] Continuing vancomycin when not warranted results in higher costs, more toxicities, and greater risk of development of VRE.[1,4,32] Of note, augmented renal clearance occurs with some frequency (approximately 16%) in patients with febrile neutropenia and has been associated with significantly higher rates of subtherapeutic vancomycin concentrations.[33] Clinicians should be alert to the need for therapeutic drug monitoring of vancomycin in patients with febrile neutropenia and should carefully monitor patient response to therapy in those receiving vancomycin or other renally excreted antimicrobials.[27,33,34]

Other antimicrobial agents, such as quinupristin–dalfopristin, linezolid, daptomycin, telavancin, and ceftaroline, should be reserved for documented infections caused by multiresistant gram-positive pathogens that are not susceptible to, or are unresponsive to, vancomycin. The role of these drugs in the routine treatment of febrile neutropenia is undetermined, and linezolid is associated with risk of myelosuppression.[1,4]

Oral Antibiotic Therapy for Management of Febrile Neutropenia

An individual patient's risk for complications of severe infection determines appropriate antibiotic therapy and the proper setting for administration (see Table 145-4).[1–3,5] Risk stratification is based on several parameters (eg, MASCC score or other tools previously mentioned) as well as response to empirical antimicrobial therapy if IV therapy is initially given.[1] Benefits of oral therapy on an outpatient basis include increased convenience and quality of life for patients and caregivers and reduced exposure to multidrug-resistant institutional pathogens.[1,2,4] Outpatient therapy of low-risk patients is common practice in most institutions. Careful patient selection obviously is required for such management strategies. Important criteria include patient and provider comfort, a history of protocol and medication compliance, caregiver support and transportation available 24 hours per day, and close proximity (less than 1 hour or less than 30 miles [48 km]) to appropriate medical care in the event of failure to respond to outpatient antibiotic therapy.[2] If a patient qualifies for oral therapy based on clinical and other factors, the first dose of oral regimen should be given in the clinic or hospital and the patient observed for at least 4 hours to ensure tolerance and clinical stability.

Because of the excellent spectrum of activity and favorable pharmacokinetics of currently available oral antibiotics, particularly the fluoroquinolones, oral antibiotics have an important role in the management of selected patients. In patients at low risk for severe or complicated bacterial infection, empirical therapy with broad-spectrum oral antibiotic agents achieves similar patient outcomes as parenteral antibiotics, with response rates of 77% to 95%.[1,3,4,28] Patients judged to be low risk with reliable follow-up may thus be appropriate candidates for oral antibiotic therapy administered on an outpatient basis.[1–4,28] Ciprofloxacin or levofloxacin in combination with amoxicillin–clavulanate (or clindamycin for penicillin-allergic patients) for enhanced gram-positive coverage has been most commonly studied for outpatient therapy in low-risk patients and is recommended by IDSA and NCCN guidelines.[1,2,4] In general, monotherapy with ciprofloxacin should be avoided due to relatively poor gram-positive activity. Levofloxacin has been used as monotherapy for outpatient treatment of low-risk patients, due to enhanced gram-positive activity, and is formally recommended by NCCN guidelines, although the IDSA guidelines recommend only combination therapy initially. If used, only the higher-dose levofloxacin 750 mg regimen should be administered in order to provide adequate activity against organisms such as *S. aureus* and *P. aeruginosa*.[1,4] Moxifloxacin has also been endorsed as a monotherapy option by NCCN guidelines; however, the lack of *P. aeruginosa* activity warrants special consideration.[4]

In patients at low risk for severe bacterial infection who were initiated on IV antibiotics, oral antibiotics may play a role in step-down therapy. Carefully selected patients with neutropenia may be safely switched from broad-spectrum parenteral therapy to oral antibiotic regimens with response rates comparable to patients remaining on IV therapy.[1,2,4,28] Patient selection criteria generally include defervescence within 72 hours of initiation of parenteral therapy, hemodynamic stability, absence of positive cultures or a discernible site of infection, and ability to take oral medications. Many of these patients are able to complete their course of therapy at home.[1,2,4,28] Changing parenteral antimicrobials to oral regimens in carefully selected patients is an acceptable practice and allows for less expensive hospitalizations and earlier patient discharges.[2]

Antimicrobial Therapy After Initiation of Empirical Therapy

⑥ After initiation of empirical antimicrobial therapy (Table 145-5), judicious assessment of febrile neutropenic patients with cancer is mandatory to evaluate response, clinical status, laboratory data, and potential need for therapy adjustments. After 2 to 4 days of empirical antimicrobial therapy, the clinical status and culture results should be reevaluated to determine whether therapeutic modifications are necessary (Fig. 145-2). Modifications of antimicrobial therapy should be based on clinical and laboratory data; antibiotic therapy should be optimized based on culture results. However, during periods of neutropenia, patients generally should continue to receive broad-spectrum therapy because of risk of secondary infections or breakthrough bacteremias when antimicrobial coverage is too narrow.[1,4] The treatment duration for a documented infection should be appropriate for the particular organism and site, and should continue for at least the duration of neutropenia (until ANC greater than or equal to 500 cells/mm^3 [0.5 × 10^9/L]) or longer if clinically necessary.

TABLE 145-5

Drug Dosing Table

Drug	Brand Name	Usual Dosing Regimen	Special Population Dose	Other

Amoxicillin–clavulanate	Augmentin®	875 mg orally every 12 hours		In combination with ciprofloxacin for outpatient treatment
Ceftazidime	Fortaz®	2 g IV every 8 hours		
Ceftazidime–avibactam	Avycaz®	2.5 g IV every 8 hours, administered over 2 hours		Not studied in febrile neutropenia, but spectrum is appropriate if high rates of MDR gram-negative bacteria (esp. CRE)
Cefepime	Maxipime®	2 g IV every 12 hours		
Ceftaroline	Teflaro®	600 mg IV every 12 hours		Activity against methicillin-resistant *S. aureus*
Ceftolozane–tazobactam	Zerbaxa®	1.5 g IV every 8 hours		Not studied in febrile neutropenia, but spectrum is appropriate if high rates of MDR gram-negative bacteria
Piperacillin–tazobactam	Zosyn®	3.375-4.5 g IV every 6 hours		
Imipenem–cilastatin	Primaxin®	500 mg IV every 6 hours		
Meropenem	Merrem®	1 g IV every 8 hours		
Meropenem/vaborbactam	Vabomere®	4 g IV every 8 hours, administered over 3 hours		Not studied in febrile neutropenia, but spectrum is appropriate if high rates of MDR gram-negative bacteria (esp. CRE)
Doripenem	Doribax®	500 mg IV every 8 hours		
Tobramycin	Nebcin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily		Traditional dosing: Guided by measured serum concentrations
Gentamicin	Garamycin®	Traditional: 2 mg/kg loading dose, followed by 1.5 mg/kg IV every 8 hours. Alternative: 5-7 mg/kg IV once daily		Traditional dosing: Guided by measured serum concentrations
Amikacin	Amikin®	Traditional: 7.5 mg/kg IV every 12 hours. Alternative: 15-20 mg/kg IV once daily		Traditional dosing: Guided by measured serum concentrations
Ciprofloxacin	Cipro®	400 mg IV every 8 hours	Outpatient treatment: 750 mg orally every 12 hours	May be given orally in low-risk patients in combination with amoxicillin–

				clavulanate
Levofloxacin	Levaquin®	750 mg IV once daily	Outpatient treatment: 750 mg orally once daily	May be given orally in low-risk patients
Moxifloxacin	Avelox®	400 mg IV/orally once daily	Outpatient treatment: 400 mg orally once daily	For select outpatient use, lacks *P. aeruginosa* activity
Delafloxacin	Baxdela®	300 mg IV or 450 mg orally every 12 hours		Activity includes methicillin-resistant *S. aureus* and *P. aeruginosa*; not studied in febrile neutropenia, but spectrum is appropriate
Vancomycin	Vancocin®	30-40 mg/kg/day IV in two divided doses administered every 12 hours		For methicillin-resistant *S. aureus* infection; dosing guided by serum concentrations to achieve trough of 15-20 mg/L (10-14 μmol/L)
Nafcillin	Nafcil®	1-2 g IV every 6 hours		For methicillin-susceptible *S. aureus* infection
Daptomycin	Cubicin®	Skin/soft tissue infections: 4 mg/kg IV once daily; bacteremia: 6 mg/kg IV once daily		For infection (esp. bacteremia) due to methicillin-resistant *S. aureus*, vancomycin-resistant enterococci
Linezolid	Zyvox®	600 mg IV or orally every 12 hours		For infection due to vancomycin-resistant enterococci
Ampicillin	Omnipen®, Polycillin®, Principen®	1-2 g IV every 4 hours		In combination with gentamicin for *Listeria* infection
Erythromycin	E-mycin®, Erythrocin®	1-2 g IV every 4-6 hours		For *Legionella* infection
Clotrimazole	Mycelex Troche®	10 mg orally five times daily		Administered as oral troche; dissolve in mouth
Nystatin	Nystatin Oral®	100,000 units orally every 4-6 hours		Administered as suspension; swish and swallow
Fluconazole	Diflucan®	800 mg IV or orally once, then 400-800 mg IV or orally once daily	Prophylaxis of *Candida* infection: 400 mg IV or orally once daily	
Itraconazole	Sporanox®	200-400 mg/day orally divided twice daily	Prophylaxis of *Candida* infection: 200 mg orally twice daily	Therapeutic drug monitoring recommended
Voriconazole	Vfend®	6 mg/kg IV every 12	Prophylaxis in high-risk patients:	Therapeutic drug monitoring

		hours for two doses, then 4 mg/kg IV or 200 mg orally every 12 hours	200 mg orally twice daily	recommended
Posaconazole	Noxafil®	Suspension: 800 mg/day orally in two to four divided doses Oral DR or IV: 300 mg every 12 hours × 2 doses, then 300 mg daily	Prophylaxis in high-risk patients: 200 mg orally three times daily	DR formulation has improved bioavailability, administered with food. Suspension: administer with full meal or enteral nutritional supplements Therapeutic drug monitoring recommended
Isavuconazonium	Cresemba®	372 mg IV/oral every 8 hours × 6 doses, then 372 mg daily		Limited clinical experience
Lipid-associated amphotericin B (LAMB)	AmBisome®, Abelcet®	3-5 mg/kg IV once daily	Prophylaxis in high-risk patients: 1 mg/kg IV once daily	
5-Flucytosine	Ancobon®	25 mg/kg/day orally every 6 hours		In combination with LAMB for cryptococcal meningitis. Therapeutic drug monitoring recommended
Caspofungin	Cancidas®	70 mg IV once, then 50 mg IV once daily		
Micafungin	Mycamine®	100 mg IV once daily	Prophylaxis in high-risk patients: 50 mg IV once daily	
Anidulafungin	Eraxis®	200 mg IV once, then 100 mg IV once daily		
Acyclovir	Zovirax®	5-10 mg/kg IV every 8 hours, or 800 mg orally two to five times daily	Prophylaxis of HSV or VZV: 800-1,600 mg orally twice daily; CMV prophylaxis in allogeneic HCT: 800 mg orally four times daily; HSV or VZV encephalitis: 10 mg/kg IV every 8 hours	
Valacyclovir	Valtrex®	1 g orally every 8 hours	Prophylaxis of HSV or VZV: 500 mg orally two or three times daily; CMV prophylaxis in allogeneic HCT: 2 g orally four times daily	
Ganciclovir	Cytovene®	CMV treatment or preemptive therapy: 5 mg/kg IV every 12 hours	CMV prophylaxis: 5-6 mg/kg IV daily 5 days/wk	

Valganciclovir	Valcyte®	CMV preemptive therapy: 900 mg orally every 12 hours for 2 weeks	CMV prophylaxis: 450-900 mg orally daily	
Foscarnet	Foscavir®	CMV treatment: 90 mg/kg IV every 12 hours for 2 weeks; CMV preemptive therapy: 60 mg/kg IV every 12 hours for 2 weeks	CMV prophylaxis: 60 mg/kg IV two or three times daily for 7 days, then 90-120 mg/kg IV daily	
Letermovir	Prevymis®	480 mg IV or PO once daily		For prophylaxis of CMV infection and disease in CMV-seropositive allogeneic HCT recipients, used through day 100 post-transplant
CMV hyperimmune globulin	Cytogam®	400 mg/kg IV every other day for three to five doses		Consider as adjunct to ganciclovir or foscarnet for treatment of CMV pneumonia; IVIG considered equally effective
Trimethoprim–sulfamethoxazole	Bactrim®, Cotrimoxazole®	Treatment of *P. jirovecii*: 15-20 mg/kg/day IV divided every 6 hours[b]	Prophylaxis of *P. jirovecii*: 160 mg/800 mg orally daily or three times per week	
Atovaquone	Mepron®	Treatment of *P. jirovecii*: 750 mg orally every 12 hours	Prophylaxis of *P. jirovecii*: 1,500 mg/day orally in one or two divided doses every 12 hours	
Pentamidine	Pentam®	Treatment of *P. jirovecii*: 4 mg/kg IV once daily	Prophylaxis of *P. jirovecii*: 300 mg by inhalation once monthly	
Clindamycin	Cleocin®	450-600 mg orally every 6 hours		In combination with primaquine for *P. jirovecii*, or with pyrimethamine for toxoplasmosis
Primaquine	Aralen®, Primaquine®	15 mg orally once daily		In combination with clindamycin for *P. jirovecii*
Dapsone	Dapsone®	100 mg orally once daily		In combination with trimethoprim for *P. jirovecii*
Trimethoprim	Triprim®	15-20 mg/kg/day orally divided every 6 hours		In combination with dapsone for *P. jirovecii*
Pyrimethamine	Daraprim®	50-100 mg orally once		In combination with sulfadiazine for

		daily[c]		toxoplasmosis
Sulfadiazine	Sulfadiazine®	1 g orally every 4-6 hours		In combination with pyrimethamine for toxoplasmosis
Thiabendazole	Mintezol®	25 mg/kg orally every 12 hours (maximum 3 g/day)		For *Strongyloides* and other intestinal worm infections

In patients who become afebrile after 2 to 4 days of therapy with no infection identified, it is generally optimal to continue antibiotic therapy until neutropenia has resolved (ANC greater than or equal to 500 cells/mm^3 [0.5 × 10^9/L]). Some clinicians switch therapy to an oral regimen (eg, ciprofloxacin plus amoxicillin–clavulanate) after 2 days of IV therapy in low-risk patients who become afebrile and have no evidence of infection. In high-risk patients, parenteral antibiotic regimens should be continued until resolution of neutropenia.[1,4] However, in afebrile patients with prolonged neutropenia but no signs or symptoms of infection, consideration can be given to discontinuing antibiotic therapy or switching to fluoroquinolone prophylaxis (discussed in "Prophylaxis of Infections in Neutropenic Patients with Cancer" below), provided that patients can be observed carefully and have ready access to medical care.

The optimal management of patients who remain febrile in the absence of microbiologic or clinical documentation of infection remains highly controversial. Persistently febrile patients should be evaluated carefully, but modifications generally are not made to initial antimicrobial regimens within the first 2 to 4 days of therapy unless there is evidence of clinical deterioration (see Fig. 145-1).[1,3,4] It is important to note that the persistence of fever does not necessarily mean failure of a given antimicrobial regimen; up to 25% of patients with neutropenia have fever due to noninfectious causes.[7] This is particularly true if patients are otherwise clinically stable. Fever after two or more days of antibiotic therapy can be due to a number of causes, including nonbacterial infection, resistant bacterial infection or infection slow to respond to therapy, emergence of a secondary infection, inadequate drug concentrations, drug fever, infection at an avascular site (eg, catheter infection or abscess), or noninfectious causes such as tumor or administration of blood products.[1,3,4] Patients with documented infection who are receiving appropriate antimicrobial therapy (based on in vitro susceptibility tests) often remain febrile until resolution of neutropenia occurs. Therefore, the same antibiotic regimen can be continued in patients who remain febrile despite 2 to 4 days of antibiotic therapy but are otherwise clinically stable, especially if neutropenia is expected to resolve within 1 week. However, antibiotic regimens may require modification in patients experiencing toxicities (Table 145-6) as well as in patients with evidence of progressive disease, clinical instability, or documentation of an organism not covered by the initial regimen.[1,3,4] If not already part of the regimen, vancomycin should be considered as warranted by clinical and laboratory findings. However, if vancomycin was included in the initial empirical regimen and the patient is still febrile after 2 to 3 days of therapy without isolating a gram-positive pathogen, discontinuation of vancomycin should be considered to reduce the risk of toxicities or resistance.[1,4]

TABLE 145-6

Drug Monitoring of Selected Antimicrobials for Febrile Neutropenia, HCT, and SOT

Drug	Adverse Reaction	Monitoring Parameters	Comments
Antibacterial Agents			
Aminoglycosides (Tobramycin, Gentamicin, Amikacin)	Nephrotoxicity	Serum creatinine, urine output, serum concentrations	Extended-interval ("once daily") dosing potentially associated with less renal toxicity, similar efficacy to traditional dosing. Goal trough concentration <1 mcg/mL (mg/L; 2 μmol/L) during extended-interval dosing
Imipenem–	CNS toxicities, seizures	Serum	Increased incidence with higher dose, failure to adjust dose/interval for reduced renal

cilastatin		creatinine, mental status, CNS function	function. Increased risk compared to meropenem or doripenem
Linezolid	Myelosuppression, thrombocytopenia, optic/peripheral neuropathy, serotonin syndrome	CBC, vision changes, serum lactate, heart rate, blood pressure, temperature, myoclonus	Myelosuppression and neuropathy more common with prolonged use. Short course unlikely to affect marrow recovery in HCT. Weak MAO inhibitor, serotonin syndrome possible with other serotonergic drugs such as SSRIs and SNRIs
Nafcillin	Interstitial nephritis	Serum creatinine, urine output	Reversible, requires switch to alternative β-lactam
Vancomycin	Nephrotoxicity, infusion reactions	Serum creatinine, urine output, blood pressure, heart rate, serum concentrations	Dose adjustment required for renal dysfunction. Pretreatment and slow infusion may decrease incidence of infusion reaction. Goal trough concentration 15-20 mcg/mL (mg/L; 10-14 µmol/L) for serious infections
Antifungal Agents			
Amphotericin B (lipid-associated)	Nephrotoxicity, hepatotoxicity, electrolyte disturbances, infusion reactions	Serum creatinine, electrolytes, LFTs, blood pressure, heart rate	Liposomal preparations associated with less renal toxicity, similar efficacy to standard preparation. Electrolyte disturbances occur before creatinine alterations. Pretreatment and slow infusion may decrease incidence of infusion reaction
5-Flucytosine	Myelosuppression, GI toxicities	CBC, GI symptoms, serum creatinine, 5-flucytosine serum concentrations	Dose adjustment required for renal dysfunction. Goal serum concentrations are peak <100 mcg/mL (mg/L; 775 µmol/L) and trough 20-40 mcg/mL (mg/L; 155-310 µmol/L)
Posaconazole	Hepatotoxicity, rash; interactions with CYP450 3A4	LFTs, skin, posaconazole serum concentrations	Poor absorption with suspension, goals of >1 mcg/mL (mg/L; 1.4 µmol/L) for treatment and >0.7 mcg/mL (mg/L; 1 µmol/L) for prophylaxis. Parenteral formulation contains SBECD, not recommended for patients with CrCL<50 mL/min (0.83 mL/s). Multiple interactions with drugs metabolized by CYP 3A4, including immunosuppressants; close monitoring needed
Voriconazole	Mental status changes, headache,	Mental status, visual function,	Mental status/visual changes associated with elevated troughs >5.5 mcg/mL (mg/L; 16 µmol/L); goal trough 1-5.5 mcg/mL (mg/L; 3-16 µmol/L) for treatment and prophylaxis,

	hallucinations, visual disturbances, hepatotoxicity, QTc prolongation; interactions with CYP450 2C9, 2C19, and 3A4	LFTs, ECG, voriconazole serum concentrations	target trough of >2 mcg/mL (mg/L; 6 μmol/L) in disease with poor prognosis. Parenteral formulation contains SBECD, not recommended for patients with CrCL<50 mL/min (0.83 mL/s). Multiple interactions with drugs metabolized by CYP enzymes, including immunosuppressants; close monitoring needed
Antiviral Agents			
Foscarnet	Nephrotoxicity, hypocalcemia	Serum creatinine, electrolytes	IV hydration prior to administration. Dose adjustment required for renal dysfunction
Ganciclovir, valganciclovir	Myelosuppression, thrombocytopenia	CBC, serum creatinine	Dose adjustment required for renal dysfunction
Antiprotozoal/Antiparasitic Agents			
Dapsone	Hemolytic anemia, hypersensitivity (fever, jaundice, eosinophilia), peripheral neuropathy	CBC, bilirubin, LFTs, muscle strength, G6PD testing before use	Higher incidence of hemolytic anemia in G6PD-deficient patients
Pentamidine (IV)	Nephrotoxicity, leukopenia, hypotension, QTc prolongation, pancreatitis, hypo/hyperglycemia	Serum creatinine, serum blood glucose, blood urea nitrogen, CBC, blood pressure, heart rate; ECG	Adequate hydration recommended
Primaquine	Hemolytic anemia	CBC, bilirubin, G6PD testing before use	Avoid use in G6PD-deficient patients (hemolytic anemia)
Pyrimethamine	Bone marrow suppression	CBC	Folinic acid 5-10 mg/day often used for prevention of bone marrow toxicity
Trimethoprim–sulfamethoxazole	Myelosuppression, hyperkalemia, rash	Serum creatinine, electrolytes, CBC, skin	Dose adjustment required for renal dysfunction

CBC, complete blood count; ECG, electrocardiogram; G6PD, glucose-6-phosphate dehydrogenase; HCT; hematopoietic cell transplantation; LFT, liver function test; MAO, monoamine oxidase; PFT, pulmonary function test; QTc, corrected Q-T interval; SBECD, sulfobutylether-β-cyclodextrin; SOT, solid-organ transplantation; SSNRI, selective serotonin–norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Therapeutic drug monitoring recommendations from Reference 30.

Initiation of Antifungal Therapy

Patients with neutropenia who remain febrile despite more than 4 to 7 days of broad-spectrum antibiotic therapy are candidates for antifungal therapy. A high percentage of febrile patients who die during prolonged neutropenia have evidence of invasive fungal infection on autopsy, even though many had no evidence of fungal disease before death.[16] Persistence of fever or development of a new fever during broad-spectrum antibiotic therapy may indicate the presence of a fungal infection, most commonly due to *Candida* or *Aspergillus* spp.[15,19,22] Blood cultures are positive in fewer than 50% of patients with neutropenia and invasive fungal infections.[21,22] Rapid, sensitive diagnostic tests for fungi such as serum β-D-glucan, galactomannan, or fungal DNA assays are available and may be considered in higher-risk patients, however, delaying initiation of antifungal therapy pending results of these tests or isolation of fungal organisms may be associated with high morbidity and mortality. The empirical addition of antifungal therapy is thus justified in this clinical setting.[1,4] Therefore, empirical antifungal therapy should be initiated after 4 to 7 days of broad-spectrum antibiotic therapy in persistently febrile patients if the duration of continued neutropenia is expected to be greater than 1 week. Administered doses must be adequate to treat undiagnosed fungal infection and prevent fungal superinfection in high-risk patients with febrile neutropenia.[1,4,21]

Evidence-based recommendations from published guidelines for management of suspected or documented fungal infections in patients with neutropenia are summarized in Table 145-2.[21,25,34] Empirical coverage for both *Candida* spp. and *Aspergillus* should be considered because these organisms are responsible for more than 90% of fungal infections in patients with neutropenia and cancer.[6,15,19,22] *Aspergillus* is also particularly common in patients with hematologic malignancies and in patients undergoing HCT. In the setting of febrile neutropenia, lipid-associated amphotericin B (LAMB) products are almost exclusively recommended over conventional amphotericin B due to reduced toxicities despite significantly higher cost without clear improvement in efficacy.[1,4,20,21,25,34] Although the use of higher doses of LAMB has been advocated in an effort to improve efficacy, lower doses (3 mg/kg) of liposomal amphotericin B may be as efficacious as higher doses (10 mg/kg) with lower cost and fewer toxicities.[4] Although LAMB products are recommended for empiric therapy of neutropenic fever when antifungal agents are desired, they are not preferred agents in patients with presumed or documented invasive fungal infections.[4,18,21]

The azole compounds are also used in the management of febrile neutropenia.[1,4,21,25,34] The azoles have replaced LAMB as preferred antifungals for many patients with FN due to the increased cost and toxicities of LAMB.[4] However, concerns regarding the emergence of *Candida* strains with decreased azole susceptibility and unclear efficacy advantages have prevented these agents from replacing amphotericin B as the clear gold standard in patients with persistent febrile neutropenia.[20,25,34] Fluconazole has good efficacy against *C. albicans* but lacks activity against molds such as *Aspergillus*. The use of fluconazole as an alternative to amphotericin B for empirical antifungal therapy is thus perhaps most appropriate in hospitals in which infections due to *Aspergillus* or non-*albicans* strains of *Candida* are not common.[1,4,20,34] If fluconazole is used as antifungal prophylaxis in patients with cancer, it should not be included in empirical antifungal regimens. Voriconazole is the preferred agent in the treatment of documented invasive fungal infections and is recommended as a reliable option for febrile neutropenia.[1,4,34] Despite failing to meet noninferiority criteria when compared against LAMB for empiric therapy in patients with febrile neutropenia, voriconazole is a preferred agent for invasive aspergillosis (especially pulmonary) due to improved survival and less toxicity when compared to amphotericin B.[1,4,20,25,34–36] Isavuconazonium, the prodrug of isavuconazole, has activity against invasive aspergillosis and mucormycosis that is generally comparable to voriconazole and posaconazole. Isavuconazonium has shown reductions in mortality and overall treatment success similar to voriconazole in a largely neutropenic patient population with hematologic malignancies and suspected invasive fungal infections including a subgroup of proven or probable aspergillosis.[37,38] The most recent guidelines recommend isavuconazonium as an alternative to voriconazole in the treatment of invasive aspergillosis, although there are few data related to use as empiric therapy of febrile neutropenia.[4,21,34] Posaconazole has extended activity against some Mucorales and rare molds in addition to *Candida* and *Aspergillus*, but is only approved for prophylaxis of fungal infections in patients with neutropenia. The improved bioavailability of the delayed-release tablets and availability of a parenteral dosage form make posaconazole an attractive option; although clinical data are relatively limited, the most recent guidelines also recommend posaconazole as an alternative to voriconazole for presumed or documented invasive disease.[21,34] Itraconazole has similar efficacy as amphotericin B, with fewer toxicities. However, current lack of a parenteral dosage form, erratic oral absorption, numerous potential drug–drug interactions, and availability of many other antifungal options limit the use of itraconazole for empiric therapy.[21,34,35] Therapeutic drug monitoring has been recommended for some azole antifungals given potential for interpatient variability, therapeutic failure associated with subtherapeutic concentrations, and toxicities associated with supratherapeutic concentrations (Table 145-6).[4,18,21,28,31,34,39]

The echinocandin antifungals (caspofungin, micafungin, and anidulafungin) are attractive agents for treatment of febrile neutropenia because of their broad spectrum of antifungal activity and favorable adverse effect profiles. Caspofungin is as effective as, and also generally better tolerated than, liposomal amphotericin B for empirical treatment of patients with neutropenia with persistent fever.[1,4] Therefore, caspofungin is considered an appropriate alternative to LAMB and voriconazole.[1,4,20,21,25] Micafungin and anidulafungin have not been as well studied specifically in this setting; however, most experts consider them likely as effective and all echinocandins are recommended.[1,4,21,25]

Initiation of Antiviral Therapy

Patients with febrile neutropenia associated with vesicular or ulcerative skin or mucosal lesions should be evaluated carefully for infection due to HSV or varicella-zoster virus (VZV). Mucosal lesions from viral infections provide a portal of entry for bacteria and fungi during periods of immunosuppression. If viral infection is presumed or documented, patients with neutropenia should receive aggressive antiviral therapy to aid healing of primary lesions and prevent disseminated disease. Acyclovir traditionally has been used in this population. However, the newer antivirals valacyclovir and famciclovir have better oral absorption and more convenient dosing schedules. Routine use of antiviral agents in the management of patients without mucosal lesions or other evidence of viral infection generally is not recommended.[1,4] Treatment recommendations for viral infections are given in Table 145-7.

TABLE 145-7

Infectious Complications During Neutropenia, and After Hematopoietic Stem Cell and Solid-Organ Transplantation: Syndromes of Disease and Treatment Guidelines

Pathogen	Syndromes of Disease	Recommended Treatment
Bacterial		
Gram-negative aerobic bacilli (Enterobacterales, *Pseudomonas aeruginosa*, *Haemophilus influenzae*)	Blood, urinary tract, pulmonary, abdomen	*Empiric:* Ceftazidime ± aminoglycoside,[a,b] cefepime ± aminoglycoside[a,b]; piperacillin–tazobactam; imipenem–cilastatin ± aminoglycoside[a,b]
		Definitive: According to culture and sensitivity results
Gram-positive cocci (*Staphylococcus aureus*, *Staphylococcus epidermidis*, *Streptococcus pneumoniae*, *Enterococcus faecalis*)	Skin, blood, urinary tract, pulmonary, abdomen	*Empiric:* Nafcillin; vancomycin
		Definitive: According to culture and sensitivity results
Legionella spp.	Pulmonary	Erythromycin; azithromycin; ciprofloxacin; levofloxacin
Listeria monocytogenes	CNS	Ampicillin with gentamicin[a]; trimethoprim–sulfamethoxazole
Nocardia spp.	Skin, pulmonary, CNS	Sulfadiazine; trimethoprim–sulfamethoxazole
Fungal		
Candida spp.[c]	Blood, urinary tract, mucous membranes, skin, disseminated disease	Clotrimazole; nystatin; fluconazole; itraconazole; amphotericin B ± 5-flucytosine; lipid-associated amphotericin B (LAMB); caspofungin; micafungin; anidulafungin
Aspergillus spp.[d]	Skin, pulmonary, CNS	Voriconazole; LAMB; caspofungin; micafungin; posaconazole; itraconazole; isavuconazole

Cryptococcus neoformans	Skin, pulmonary, CNS	LAMB + 5-flucytosine; fluconazole
Mucorales (*Mucor*)	Rhinocerebral disease	LAMB; posaconazole
Viral		
Herpes simplex virus	Skin, CNS, mucous membranes, pulmonary	Acyclovir; foscarnet
Human herpesvirus-6	CNS, hepatic, bone marrow	Ganciclovir; foscarnet
Cytomegalovirus	Pulmonary, blood, urinary tract, GI tract	Ganciclovir; foscarnet; immunoglobulin
Varicella-zoster virus	Skin, disseminated disease	Acyclovir; foscarnet
Epstein–Barr virus	Lymphoproliferative disease	Rituximab
Papovaviruses (BK, JC)	Skin, CNS	No effective treatment
Protozoal/Parasitic		
Pneumocystis jirovecii	Pulmonary	Trimethoprim–sulfamethoxazole; atovaquone; pentamidine; dapsone + trimethoprim; clindamycin + primaquine
Toxoplasma gondii	CNS	Pyrimethamine + sulfadiazine; pyrimethamine + clindamycin
Strongyloides stercoralis	Pulmonary, CNS	Thiabendazole

[a] Choice of specific agent determined according to institutional susceptibilities to individual drugs.

[b] For penicillin-allergic adults, use aztreonam or ciprofloxacin + an aminoglycoside.

[c] Refer to the Clinical Practice Guidelines of the Infectious Diseases Society of America (*Reference 21*) for selection and dosing of antifungal agents for specific infections.

[d] Refer to the Clinical Practice Guidelines by the Infectious Diseases Society of America (*Reference 25*) for selection and dosing of antifungal agents for specific infections.

Duration of Antimicrobial Therapy

⑦ The optimal duration of antimicrobial therapy in patients with cancer and neutropenia remains controversial. Decisions regarding discontinuation of empirical antimicrobial therapy often are more difficult and complex than those regarding initiation of therapy (see Figs. 145-1). One point on which experts agree, however, is that the most important determinant of the total duration of antibiotic therapy is the patient's ANC.[1,4] If ANC is greater than or equal to 500 cells/mm^3 (0.5 × 10^9/L) for 2 consecutive days, if the patient is afebrile and clinically stable for 48 hours or more, and if no pathogen has been isolated, then antibiotics can be discontinued. Some clinicians advocate that patients with ANC less than 500 cells/mm^3 (0.5 × 10^9/L) be maintained on antibiotic therapy until resolution of neutropenia, even if they are afebrile. However, prolonged antibiotic use has been associated with superinfections resulting from resistant bacteria and fungi and increases the risk of antibiotic-related toxicities.[1,4] If low-risk patients are clinically stable with negative cultures but the ANC still is less than 500 cells/mm^3 (0.5 × 10^9/L), antibiotics may be discontinued after a total of 5 to 7 afebrile days. However, patients with profound neutropenia (ANC greater than 100 cells/mm^3 [0.1 × 10^9/L]), mucosal lesions, or unstable vital signs or other risk factors should continue to receive antibiotics until ANC has increased greater than or equal to 500 cells/mm^3 (0.5 × 10^9/L) and the patient is clinically stable.[1,4]

Patients who are persistently neutropenic and febrile, but who are stable clinically with no active site of infection, often can be successfully discontinued from antimicrobials after at least 2 weeks of therapy. However, these patients must be monitored carefully because reinstitution of antibiotics may be necessary.[1,4] An alternative approach is to place these patients on antimicrobial prophylaxis (discussed in the section “Prophylaxis of Infections in Neutropenic Patients with Cancer” below). Patients with documented infections should receive antimicrobial therapy until the infecting organism is eradicated and signs and symptoms of infection have resolved (at least 10-14 days of therapy).

Consensus guidelines provide useful information regarding the management of febrile episodes in patients with cancer and neutropenia.[1,4] However, therapy (including initial empirical regimens, modifications, and duration of treatment) must be individualized based on specific patient parameters and response to therapy.

Colony-Stimulating Factors

Because resolution of neutropenia is arguably the most important determinant of patient outcome from both febrile episodes and documented infections, numerous studies have evaluated hematopoietic colony-stimulating factors (CSFs) (sargramostim [granulocyte-macrophage colony-stimulating factor] and filgrastim [granulocyte colony-stimulating factor]) as adjunct therapy to antimicrobial treatment of febrile neutropenic patients with cancer. A meta-analysis found that use of CSFs is associated with reduced total duration and severity of chemotherapy-related neutropenia, reduced duration of antibiotic use, fewer hospitalizations, and decreased hospital length of stay.[40] However, this meta-analysis failed to demonstrate a benefit of CSFs in relation to important outcomes such as decreased overall mortality or infection-related mortality.[40] Evidence-based guidelines from the IDSA, American Society of Clinical Oncology (ASCO), and the NCCN recommend that CSFs should not be routinely initiated in patients with uncomplicated fever and neutropenia.[1,4,41,42] However, CSFs should be considered in patients who are at high risk for infection-associated complications, or who have factors that are predictive of poor clinical outcomes.[4,41,42] These factors are summarized in Table 145-8. Patients with prolonged neutropenia and documented severe infections who are not responding to appropriate antimicrobial therapy may also benefit from treatment with CSFs.[41,42] Clinical judgment must be exercised in determining which patients may benefit from judicious use of these expensive agents.

TABLE 145-8

Recommendations for Use of Colony-Stimulating Factors in the Management of Patients with Cancer and Those Undergoing Stem Cell Transplantation

Primary prophylaxis of febrile neutropenia

1. Colony-stimulating factors (CSFs) (filgrastim, pegfilgrastim, or sargramostim) may be considered in patients who have a high risk of febrile neutropenia (>20% incidence) based on myelotoxicity of the planned chemotherapy regimen.
2. When risk of febrile neutropenia is 10%-20%, CSFs may be considered in the presence of certain patient and clinical factors predisposing to increased complications from prolonged neutropenia, including patient age >65 years; poor performance status; extensive prior treatment including large radiation ports; administration of combined chemoradiotherapy; cytopenias due to bone marrow involvement by tumor; poor nutritional status; presence of open wounds or active infections; previous surgery; poor renal function; liver dysfunction, particularly when evidenced by increased bilirubin; and lack of antibiotic prophylaxis.

Secondary prophylaxis of febrile neutropenia

1. CSFs (filgrastim, pegfilgrastim, or sargramostim) recommended for patients who experienced neutropenic complications from prior cycles of chemotherapy, and in which a reduced dose may compromise disease-free or overall survival or treatment outcome.

Therapeutic use in febrile neutropenia

1. CSFs should not be routinely used for patients with neutropenia who are afebrile.
2. CSFs (filgrastim or sargramostim only) may be considered in patients with febrile neutropenia who are at high risk for infection-associated complications, or who have prognostic factors that are predictive of poor clinical outcomes, including profound neutropenia (absolute neutrophil count <100 cells/mm^3 [0.1×10^9/L]); expected prolonged period of neutropenia (>10 days); patient age >65 years; uncontrolled primary disease; sepsis syndrome, or severe infection manifest by hypotension and multiorgan dysfunction; pneumonia; invasive fungal infection; other clinically documented infection; hospitalized at the time of the development of fever; or severe complications during previous episode of febrile neutropenia.

Reduction in duration of neutropenia in HCT

1. CSFs are recommended to mobilize peripheral-blood progenitor cells (PBPC) prior to chemotherapy and to reduce the duration of neutropenia after autologous PBPC transplantation.

Data from References 4,39,40.

Direct transfusion of neutrophils has also been studied for treatment of febrile neutropenia or documented infections.[5,43] Routine use of neutrophil transfusions is not generally supported by data demonstrating improved clinical outcomes. However, use may be considered in patients with profound prolonged neutropenia with severe documented infections and in whom causative organisms have not been eradicated with appropriate antimicrobial therapy in combination with CSFs.[4] At present, the use of neutrophil transfusions is not recommended for routine management of patients with febrile neutropenia.[4]

Prophylaxis of Infections in Neutropenic Patients with Cancer

⑧ Owing to the potential morbidity and mortality of infections in neutropenic cancer patients, environmental modifications and prophylactic antimicrobial regimens have been implemented to prevent these complications. The overall goal of antimicrobial prophylaxis in patients with cancer is to decrease the number and severity of systemic infections during prolonged periods of neutropenia. As with febrile neutropenia, patient risk factors for development of infection and complications should be assessed prior to initiation of prophylaxis (Table 145-9).

TABLE 145-9

Risk-Based Prophylactic Strategies for Patients with Neutropenia

Risk Group	Patient Characteristics	Prophylactic Strategies
High risk	- *Neutropenia:* Severe (absolute neutrophil count <100/mm^3 [0.1 × 10^9/L]) and/or prolonged (≥10 days) - *Malignancy/treatment:* Hematologic malignancy (acute leukemia), allogeneic HCT, GVHD with high-dose steroids (≥20 mg prednisone equivalents daily for ≥1 month), or use of alemtuzumab or purine-containing regimens	Consider bacterial prophylaxis with fluoroquinolone for duration of neutropenia. Give fungal prophylaxis with product and duration based on patient-specific factors. Give/consider viral prophylaxis with product and duration based on patient-specific factors. Consider protozoal prophylaxis with product and duration based on patient-specific factors
Moderate risk	- *Neutropenia:* Moderate duration (7-10 days) - *Malignancy/treatment:* Autologous HCT, multiple myeloma, lymphoma, chronic lymphocytic leukemia, purine analog therapy	Consider bacterial prophylaxis with fluoroquinolone for duration of neutropenia. Consider fungal prophylaxis with product and duration based on patient-specific factors. Give/consider viral prophylaxis with product and duration based on patient-specific factors. Consider protozoal prophylaxis with product and duration based on patient-specific factors
Low risk	- *Neutropenia:* Short duration (≤7 days) - *Malignancy/treatment:* Solid tumor treated with conventional chemotherapy	Antibacterial and antifungal prophylaxis not indicated. Viral prophylaxis considered during neutropenia if patient has prior HSV episode

GVHD, graft versus host disease; HCT, hematopoietic stem cell transplant; HSV, herpes simplex virus.

Data from References 1,4,6,27,37,42.

General Measures

Because approximately 50% of pathogens infecting neutropenic cancer patients are acquired in the hospital, reducing acquisition of infectious organisms from the environment is a basic component in controlling nosocomial infections.[1,4,6] Patients with neutropenia should be placed in reverse isolation (isolation to protect patients from contracting infections after exposure to others) with standard barrier precautions, and strict adherence to infection prevention guidelines by hospital personnel.[1,4,6] Plants and fresh or dried flowers are usually prohibited as part of standard neutropenic precautions in order to minimize risk of exposure to pathogenic bacteria. Proper handwashing and respiratory hygiene by hospital personnel are simple yet effective infection prevention measures.[44] Most patients with neutropenia do not require specific room ventilation; however, HCT recipients should be placed in a private positive-pressure room with greater than 12 air exchanges per hour and HEPA filtration.[1,4,6]

Bacterial Infections

Combinations of oral nonabsorbable antibiotics, such as gentamicin, nystatin, vancomycin, polymyxin B, and colistin, have been widely studied as a means of reducing colonization of the GI tract with virulent pathogens. Although selective intestinal decontamination with oral nonabsorbable antibiotics successfully reduces infections, these regimens are not routinely recommended for prophylaxis because of problems that include unpalatability, cost, frequent adverse effects (eg, nausea, vomiting, and diarrhea), and development of resistance.[1–6]

Prophylaxis with orally administered, systemically available antibiotics such as trimethoprim–sulfamethoxazole and fluoroquinolones is effective at reducing gram-negative infections.[1,4] Although trimethoprim–sulfamethoxazole is effective as prophylaxis against *P. jirovecii*, its lack of activity against

P. aeruginosa is worrisome when used as prophylaxis against bacterial infection, particularly in institutions where pseudomonal infections are frequent.[1] Other concerns with trimethoprim–sulfamethoxazole prophylaxis include selection of resistant organisms, predisposition to development of oral fungal infections, and delay in bone marrow recovery resulting in prolonged neutropenic episodes.[1,4,6]

Fluoroquinolones are more effective than placebo in preventing febrile episodes and gram-negative infections in neutropenic cancer patients and, in some studies, have decreased all-cause mortality and infection-related mortality.[1,4,6,45] However, there are several potential limitations to their use. In particular, ciprofloxacin may lack adequate gram-positive activity and may not be the preferred fluoroquinolone for this reason. Although fluoroquinolone prophylaxis has been associated with colonization and infection with fluoroquinolone-resistant gram-negative organisms, these findings have not been consistent in various studies.[1,4,11,45] The risk of colonization or infection with strains resistant to the prophylactic agent is also lower with fluoroquinolones compared to trimethoprim–sulfamethoxazole.[36] However, patients experiencing breakthrough infection during fluoroquinolone prophylaxis should not be subsequently placed on a fluoroquinolone-containing empirical antibiotic regimen.[1,4] Although studies have not consistently documented increased fluoroquinolone resistance in association with prophylaxis, other potentially unfavorable outcomes such as increased risk of *Clostridioides difficile* infection should also be considered in weighing the potential benefits of fluoroquinolone prophylaxis.[1,4,11,36,45]

Although the benefits of prophylaxis with fluoroquinolones outweigh the potential risks in patients with neutropenia who are at intermediate to high risk for infection (Table 145-9), antibacterial prophylaxis in general remains somewhat controversial due to continued concerns regarding the potential for development of resistant bacteria, high cost, and lack of consistent benefits related to patient survival.[1,4,11] Therefore, antibacterial prophylaxis is not recommended routinely for all patients with neutropenia. Prophylaxis with ciprofloxacin or levofloxacin generally is indicated for intermediate- to high-risk patients expected to be profoundly neutropenic for more than 1 week as shown in Table 145-9.[1,4,6,44] Fluoroquinolone prophylaxis is not routinely recommended for patients with solid tumors.[23,27,44] High-dose levofloxacin may be preferred by some clinicians due to enhanced gram-positive activity. An oral cephalosporin (cefpodoxime) may be considered for patients intolerant of fluoroquinolones.[44] Neutrophil recovery eliminates the need for continued prophylaxis, and recovery may be facilitated by use of CSFs.[41] CSFs have also been formally recommended by ASCO and NCCN for primary prevention of FN in high-risk patients (see Table 145-8).[1,4]

Fungal Infections

Because patients with neutropenia are at risk for mucocutaneous and invasive fungal infections that are difficult to diagnose and treat, antifungal prophylaxis can be considered in intermediate- to high-risk patients at institutions where fungal infections in patients with cancer occur frequently.[1,4] The goal of antifungal prophylaxis is to prevent development of invasive fungal infections during periods of risk, thereby reducing morbidity and mortality. Similar to antibacterial prophylaxis, prophylaxis against fungal infection is specifically recommended for patients who are at risk for profound, protracted neutropenia (Table 145-9).[4,6,23,44]

Antifungal prophylaxis with an oral triazole agent (fluconazole, itraconazole, voriconazole, posaconazole, isavoconazole), parenteral echinocandin, or LAMB is recommended in select patients starting at the time of induction chemotherapy.[4,44] Fluconazole prophylaxis has been particularly well studied and reduces the incidence of both superficial and systemic fungal infections; it also significantly decreases mortality from fungal infections in patients with leukemia and HCT recipients.[4,38] However, use of fluconazole prophylaxis has contributed to the emergence of infections caused by *C. krusei* and *C. glabrata*, pathogens that frequently are resistant to fluconazole and other azole-type antifungal agents.[4,23] When compared to prophylaxis with mold-active agents, patients on fluconazole have a higher rate of aspergillosis and invasive fungal-related mortality but lower rate of adverse events leading to discontinuation.[37] The choice of a specific agent should be determined by the types of fungal isolates at individual institutions and risk for invasive mold infection compared to invasive candidiasis.[1,4,21,44,46] After initiation, antifungal prophylaxis should be continued until resolution of neutropenia or the need for institution of antifungal therapy for suspected/documented infection.[4,18,21,23,44]

Other Infections

Use of trimethoprim–sulfamethoxazole prophylaxis in patients with cancer at risk for *P. jirovecii* pneumonia has substantially reduced the incidence of this infection. Trimethoprim–sulfamethoxazole is therefore recommended for use in patients receiving higher-risk chemotherapeutic regimens (see

Table 145-9).[1,4,44] Antiviral prophylaxis with acyclovir, valacyclovir, or famciclovir is recommended to reduce the risk of HSV reactivation in patients with acute leukemia undergoing intensive chemotherapy.[4,44] Prophylaxis with a nucleoside reverse transcriptase inhibitor such as entacavir or tenofovir is recommended for patients at high risk of HBV reactivation.[4,44] Finally, patients should be assessed for indications for administration of vaccines such pneumococcal, influenza, varicella, and varicella zoster in order to provide protection from vaccine-preventable infections that commonly occur in patients with neutropenia and immunosuppression.[38] Many vaccines will be most effective when administered to patients prior to beginning immunosuppressive chemotherapy regimens, while inactivated influenza vaccine may also be administered to already immunocompromised patients.[38]

When considering use of antimicrobial (antibacterial, antifungal, and antiviral) prophylaxis in patients with neutropenia and cancer, the risks and benefits of prophylaxis must be weighed against issues with development of resistance, toxicities, and other concerns.

Evaluation of Therapeutic Outcomes

⑩ Close monitoring of patients with febrile neutropenia, including both clinical and laboratory parameters, is essential for early detection and treatment of infectious complications. Three general therapeutic outcomes have been defined in the setting of febrile neutropenia: (a) success (survival during the febrile episode until resolution of neutropenia by judicious selection of empirical antimicrobial therapy), (b) success with modification (same as [a] but with additions/modifications to empirical therapy), and (c) failure (death during febrile neutropenia).[1] Because many of the drugs that can be used in this setting (eg, aminoglycosides and amphotericin B) have significant toxicity potential, careful attention must be paid to prevention and management of drug-related adverse effects. Evaluations of the parameters given in the Clinical Presentation are appropriate to help monitor and guide therapy. In addition, the NCCN guidelines for febrile neutropenia provide comprehensive recommendations on clinical/laboratory monitoring parameters, including schedules.[4] The reader is referred to individual chapters within this book for more detailed discussions of monitoring parameters related to specific types of infections (eg, pneumonia and urinary tract infections).

INFECTIONS IN PATIENTS UNDERGOING HCT

① Infection remains a major barrier to successful HCT.[47–50] Recipients of HCT are at enhanced risk for infection because of prolonged periods of neutropenia. In addition, patients receiving allogeneic transplants (related, matched unrelated, or cord blood) receive prolonged immunosuppressive drug therapy for prevention and treatment of graft-versus-host disease (GVHD) following engraftment. Allogeneic HCT recipients are generally slower to engraft when compared to autologous HCT recipients.[4] Intensive pretransplant conditioning regimens (high-dose chemotherapy and total-body irradiation), as well as GVHD itself, often disrupt protective barriers, such as mucous membranes, skin, and the GI tract, placing patients at further risk of infection.[4,48,49] Although infectious complications are still associated with considerable morbidity and mortality, studies have documented significant reduction in mortality after HCT in association with reductions in disease caused by bacterial, fungal, and viral infections.[4] As the number of HCTs performed increases and patients live longer, the population of HCT recipients is expected to continue to grow exponentially.[42]

Etiology and Clinical Presentation of Infections

② ⑩ The timing with which specific types of infections typically occur following HCT is shown in Fig. 145-3, but the relative incidence and importance of specific pathogens vary greatly according to the specific type of HCT performed. Patients receiving allogeneic transplants are at greatest risk for infection after HCT and are predisposed to earlier and more severe infections with opportunistic pathogens such as *Aspergillus*. The presence of GVHD also has an impact on the incidence and timing of various infections, including invasive fungal infections.

FIGURE 145-3

Timetable for the occurrence of infections in hematopoietic stem cell transplantation (HCT) and solid-organ transplant patients. (UTI, urinary tract infection)

After administration of intensive conditioning regimens to eliminate malignant cells and prevent rejection of donor cells, patients may remain profoundly neutropenic for 3 to 4 weeks. During this pre-engraftment period, patients are at risk for the same types of infectious complications that occur in other granulocytopenic patients with cancer (eg, bacterial and fungal infections) and should be managed accordingly (see Table 145-1).[4] Table 145-7 lists regimens for treatment of specific infections.

HCT recipients remain at high risk for infection after bone marrow engraftment has occurred.[4] Significant defects in neutrophil function and cell-mediated and humoral immunity, persisting for several months after transplantation, predispose patients to infectious complications. Furthermore, specific medications, regimens, and therapies utilized are associated with added risk or a prolonged risk of various infections (alemtuzumab, anti-CD20 antibodies, fludarabine, steroids, asplenia, etc.).[4] Acute and chronic GVHD following allogeneic HCT also results in prolonged periods of immunosuppression.[4,48,49] Those who experience acute GVHD had a 60% higher infection rate and higher risk of developing serious or fatal infections compared to allogeneic HCT recipients without acute GVHD.[49] Even in the absence of active GVHD, 10% to 20% of all deaths are attributable to infection after year two in allogeneic HCT recipients.[51]

HCT recipients are at significant risk for serious bacterial infections at various sites.[4,50] Bacteremia is particularly concerning following allogeneic HCT as those with GVHD have a three-fold increased risk.[48] Bacteremia has been reported in up to half of HCT recipients with gram-positive and gram-negative bacteremia occurring at similar rates.[48,50,52] However gram-negative bacteremia remains of significant clinical importance because mortality rates may reach 45% for increasingly common multidrug resistant strains.[11] *Clostridioides difficile* has become a common and important cause of gastrointestinal infections.[4,41,50]

Fungal infections, especially those caused by *Candida* and *Aspergillus* spp., are serious and often result in fatal complications. Fungi remain a serious cause of infection, particularly in allogeneic HCT recipients, for up to 1 to 2 years following transplantation and may occur in as many as 20% of patients.[4,52,54] Significant mortality is associated with invasive aspergillosis (up to 60%) and mucormycosis infections.[4] HCT recipients are also at risk for serious viral infections, particularly HSV and cytomegalovirus (CMV). HSV infections may include gingivostomatitis, esophagitis, genital lesions, and, rarely, pneumonia during the first month after transplant.[4,55] Clinical disease is more common in patients with serologic evidence of prior exposure and latent HSV infection pretransplant. Therefore, reactivation of latent disease during periods of immunosuppression is the most common etiology of HSV infection. Without prophylaxis, as many as 80% of HSV-seropositive patients experience mucocutaneous disease after intensive chemotherapy compared with less than 25% of seronegative patients.[4,55] HSV infections often coexist with *Candida* infection and mucositis secondary to chemotherapy, radiation, or both.[4,55] Painful swallowing associated with these conditions often makes it difficult for patients to take oral medications and maintain adequate nutritional intake. Because of the considerable morbidity associated with HSV reactivation after transplantation, the HSV serologic status of patients should be determined prior to transplant.

HCT recipients are at high risk for CMV infections during the early postengraftment period. Infections range in severity from asymptomatic infection with viral shedding (urine, throat, and lungs), to life-threatening disseminated disease and interstitial pneumonia.[4,55] As with HSV, patients seropositive for CMV before transplantation are at high risk for reactivation of infection during periods of immunosuppression; up to 60% of seropositive patients develop reactivation after transplantation compared with only 3% of seronegative patients.[4,55] Other risk factors for CMV infection in HCT recipients include advanced age, human lymphocyte antigen mismatch, total-body irradiation, multiagent conditioning regimens, and presence of GVHD.[4,55] Patients without evidence of latent CMV infection (CMV-seronegative) before transplantation may develop primary CMV infection after receiving bone marrow or blood products from CMV-seropositive donors. Although the typical onset of both primary and recurrent CMV infection is 1 to 2 months after transplantation, late-onset infections may occur more than 100 days after transplantation.[4,55,56] Patients receiving allogeneic transplants are at highest risk for CMV reactivation, with progression to clinical disease in approximately 10% to 30% of patients.[4,55] The most serious clinical manifestation of CMV disease is interstitial pneumonia, which is associated with a mortality rate greater than 50% even when treated.[45] Interstitial pneumonia also may result from other infectious (*P. jirovecii*, VZV) and noninfectious causes (pulmonary damage by radiation and chemotherapy).[4,55] This clinical syndrome manifests as fever, dyspnea, hypoxia, nonproductive cough, and diffuse pulmonary infiltrates. As many as 40% of allogeneic HCT recipients will develop some form of interstitial pneumonia; a leading cause of infectious death in HCT recipients and a significant proportion are viral in etiology.[45]

During the late postengraftment period (beginning approximately 180 days after transplantation), infections remain a major problem in patients suffering from chronic GVHD. Infections common during the late postengraftment period include those caused by encapsulated bacteria, such as *S. pneumoniae* and *H. influenzae*, fungi, and viruses, including CMV and VZV.[4,54] Patients not undergoing allogeneic transplantation or suffering from chronic GVHD generally have few infections in this period.

Up to 60% of allogeneic patients with a history of VZV who survive up to 10 months after transplantation will develop VZV disease.[4,54,55] Infection with VZV is most common in allogeneic HCT recipients with acute or chronic GVHD.[54,55] Both primary (varicella) and recurrent disease (herpes zoster) usually present as skin lesions, most of which remain contained to local areas; however, 30% of these infections may disseminate to other cutaneous areas or body organs, causing severe morbidity or mortality.[4,45,55,57]

PREVENTION AND TREATMENT

Desired Outcomes

The goals of therapy in managing HCT recipients from the neutropenic period through the late postengraftment period are: (a) protect the patient from early death caused by undiagnosed infection; (b) employ effective prophylactic therapy to prevent common bacterial, fungal, viral, and protozoal/parasitic infections; (c) effectively and aggressively treat established infections; (d) avoid unnecessary use of antimicrobials that contribute to increased resistance; and (e) minimize toxicities and cost while increasing patient quality of life.

Prophylaxis and Management of Infections in Recipients of HCT

⑧ ⑨ The overall goal of prophylaxis and treatment of infection in HCT recipients is prevention of infectious morbidity and mortality. Specific goals of antimicrobial use in HCT recipients include (a) prevention of bacterial, fungal, viral, and protozoal infections during pre-engraftment and postengraftment periods and (b) effective treatment of established infections. These goals must be achieved at the lowest possible toxicity and cost. Prophylactic therapy should be aimed specifically at pathogens known to cause a high incidence of infection within the HCT population in general and within the specific institution. In addition, prophylactic therapy should be limited to regimens proved to be effective through well-designed clinical trials.

Appropriate immunizations should be a primary consideration in the prevention of infections in HCT recipients. Immunizations against common bacterial and viral pathogens are timed to avoid periods of severe immunosuppression following HCT when the protective response to vaccination potentially would be decreased.[4,58] Recommended vaccines for immunization of HCT recipients include three doses each of diphtheria–pertussis–tetanus (or diphtheria–tetanus), inactivated polio, conjugated *H. influenzae* type b, and conjugated 13-valent pneumococcal; two doses each of hepatitis A and HBV; and one dose of meningococcal conjugate vaccine 6 to 12 months post-transplant. One dose of the 23-valent pneumococcal vaccine should follow after 12 months. The influenza vaccine should be resumed at least 4 to 6 months after transplantation, and continued annually for life. Family members, close contacts, and healthcare providers of HCT recipients also should be vaccinated annually against influenza. The injectable inactivated influenza vaccine is preferred both before and after HCT due to severe underlying illnesses pretransplant and contraindication of the live-attenuated intranasal product post-transplant.[4,54,58] Finally, the live-attenuated measles–mumps–rubella vaccine should be administered no sooner than 24 months after HCT if the patient is considered to be immunocompetent.[44,48,54,58]

The live-attenuated varicella vaccine may be considered in patients seronegative for VZV owing to the risk of primary VZV infection, but if administered should be given no sooner than 24 months after transplant.[4,54,58] Shingrix® (recombinant zoster vaccine) is approved for immunocompetent adults and is effective at preventing herpes zoster, post-herpetic neuralgia, and herpes zoster related complications and related hospitalizations.[49] Shingrix® is also currently recommended by the Centers for Disease Control for prevention of zoster in immunocompromised individuals and may also be considered for patients undergoing HCT.[50]

Bacterial Infections

Prophylaxis of infections in HCT recipients is similar in many ways to that used in other patients with neutropenia. Oral antibacterial prophylaxis is used commonly; considerations are the same as those discussed in the “Prophylaxis of Infections in Neutropenic Patients with Cancer” section. Although rates of bacteremia and other bacterial infections after HCT are decreased with prophylaxis, overall mortality rates have not been consistently reduced.[2,4,54,61] Therefore, routine use of prophylactic antibiotics in HCT is somewhat controversial but should be considered in patients at moderate-to-high risk of infection (Table 145-9). Fluoroquinolones are the most frequently used agents, with levofloxacin preferred over ciprofloxacin due to enhanced gram-positive activity.[4] For those intolerant to a fluoroquinolone, cefpodoxime or trimethoprim–sulfamethoxazole may be considered.[2,4] These regimens usually are started either within 72 hours of beginning the chemotherapy conditioning regimens or on the day of hematopoietic stem cell infusion and continued throughout the neutropenic period. Patients who become febrile while receiving prophylaxis should be managed according to general guidelines for febrile neutropenia.

Antibiotic prophylaxis against bacterial infection is also recommended in the late postengraftment period (greater than 100 days after transplantation) in certain high-risk patients, specifically allogeneic HCT recipients with chronic GVHD.[4] Antibiotics should be targeted against encapsulated bacteria, particularly *S. pneumoniae*, and should be selected based on local susceptibility patterns for these organisms; penicillin is preferred in areas with low rates of penicillin-resistant pneumococci.[4] Patients receiving trimethoprim–sulfamethoxazole for prophylaxis of other opportunistic infections may be adequately protected and do not necessarily require an additional antibiotic, though the addition of penicillin may be considered.[4] Prophylaxis should be continued as long as the chronic GVHD is being actively treated.

Viral Infections

Prophylaxis of recurrent HSV infection is recommended for all HSV-seropositive patients undergoing HCT.[2,4,55] Approximately 0% to 10% of HSV-seropositive patients receiving acyclovir experienced viral shedding, clinical symptoms of viral reactivation, or both compared with 60% to 80% of patients receiving placebo.[4,55] Many patients eventually require IV acyclovir because of the development of severe mucositis from conditioning regimens. However, oral acyclovir, valacyclovir, or famciclovir is effective and considerably less expensive in patients who can take oral medications. Valacyclovir has replaced acyclovir as first-line therapy in current guidelines. The antiviral agent usually is started at the time of the conditioning regimen and continued until bone marrow engraftment or resolution of mucositis (approximately 30 days after HCT), although longer durations of prophylaxis should be considered in allogeneic HCT recipients with GVHD or frequent HSV reactivations before transplantation.[2,4,55] In addition to preventing recurrence of HSV disease, acyclovir prophylaxis may reduce the incidence of CMV reactivation.[4,54] Patients receiving ganciclovir or foscarnet for prophylaxis or treatment of CMV infection do not need additional antiviral therapy for prevention of HSV or VZV.[4,55] Patients developing active HSV or VZV infection should be treated with high-dose acyclovir.[4,45,55–57]

Oral acyclovir or valacyclovir given for up to 12 months after transplantation also significantly reduces reactivation of VZV infections and prevents the occurrence of severe VZV disease.[2,4] Patients receiving either allogeneic or autologous HCT may therefore be considered for long-term (up to 1 year after transplantation) prophylaxis against VZV.[2,4] Immunocompromised, nonimmune patients exposed to chickenpox or shingles should receive varicella-zoster immunoglobulin 625 units intramuscularly within 10 days (ideally as soon as possible) after close contact with persons with chickenpox or shingles for prevention of VZV-related disease.[52]

Acyclovir-resistant HSV has been reported occasionally in HCT recipients receiving acyclovir prophylaxis. Foscarnet is a drug of choice for treatment of documented infection with acyclovir-resistant HSV and should be reserved for this use.[4,45,55]

Prevention of CMV disease is a well-accepted indication for prophylaxis in HCT recipients because of the high associated infectious morbidity and mortality. If possible, CMV-seronegative patients should receive donor cells and supportive blood products from seronegative donors only; however, CMV-seropositive patients are not at significant additional risk by receiving blood or donor cells from seropositive donors.[57] Although acyclovir has relatively poor in vitro activity against CMV, a decrease in CMV infection and an improvement in overall survival were reported in HSV- and CMV-seropositive allogeneic HCT recipients receiving IV acyclovir.[4,45,55]

Ganciclovir has been well studied for prophylaxis with HCT because of its superior activity against CMV compared with acyclovir.[4,54] Oral valganciclovir has excellent pharmacokinetics, produces serum levels of ganciclovir that are at least similar to those achieved after IV administration, and is routinely used in many centers due to the convenience of oral dosing in certain patients.[4,54,55] Although administration of prophylactic valganciclovir to CMV-seropositive patients may significantly decrease the occurrence of CMV viremia, there is no clear survival benefit compared to a preemptive approach (ie, initiating IV ganciclovir or valganciclovir only after detecting a specific threshold of CMV copies from blood or bronchoalveolar fluid), and ganciclovir-related bone marrow suppression is frequently problematic.[53] Therefore, a preemptive approach is generally preferred over a ganciclovir prophylaxis strategy.[4,54,55] Preemptive therapy with ganciclovir and valganciclovir remains a current standard of therapy.[4,54,55] Detection of CMV is typically done by quantitative polymerase chain reaction (PCR)-based tests. Preemptive therapy significantly reduces the occurrence of CMV disease (including CMV pneumonia) and significantly improves survival up to 180 days after transplantation.[4] Because CMV viremia and PCR-positive bronchoalveolar lavage are highly predictive of subsequent CMV disease, preemptive ganciclovir or valganciclovir therapy should be considered for autologous HCT recipients within the first 100 days after transplantation or in allogeneic HCT recipients at any time after transplantation.[4] The doses of ganciclovir or valganciclovir for preemptive therapy are the same as those used for prophylaxis. Foscarnet can also be used for either prophylaxis or preemptive therapy of CMV disease in patients intolerant of ganciclovir or in the setting of ganciclovir resistant CMV.

CMV prophylaxis (rather than preemptive therapy) may be considered for specific allogeneic HCT recipients for the first 100 days after transplantation.[44] Letermovir is a highly active inhibitor of CMV replication approved for prophylaxis (but not treatment) of CMV infection and disease in CMV-seropositive recipients undergoing allogeneic HCT. In allogeneic HCT recipients assigned to letermovir or placebo, letermovir prophylaxis for a median of 82 days posttransplant substantially reduced CMV infections and disease within the first 6 months after transplant. Unlike ganciclovir, letermovir is not associated with bone marrow suppression and is therefore becoming an agent of choice for CMV prophylaxis in high-risk HCT recipients.[46] Clinical practice guidelines recommend that letermovir may be considered for primary prophylaxis of CMV disease in CMV-seropositive allogeneic HCT recipients.

Prophylaxis of CMV disease with either IV immunoglobulin (IVIG) or CMV hyperimmune globulin (CMVIG) has demonstrated variable and inconclusive benefits, and their use is not currently recommended.[4]

Ganciclovir and valganciclovir are the drugs of choice for treatment of active CMV infection in HCT recipients (see Table 145-6). Foscarnet also may be used for treatment or prevention of infections in HCT recipients as an alternative to ganciclovir/valganciclovir because of its relative lack of bone marrow toxicity or in cases of resistant CMV. Foscarnet-related nephrotoxicity is often problematic, however, especially in the post-transplant period when patients may be receiving other nephrotoxic agents. Cidofovir has not been well studied in HCT recipients and is also associated with nephrotoxicity, but this agent may also be considered for preemptive therapy or treatment of active disease as a third-line option.[4]

Numerous combination treatments such as interferon plus ganciclovir have been used unsuccessfully for treatment for CMV pneumonitis. However, the combination of high-dose IVIG and ganciclovir may decrease the mortality of the syndrome from 85% to 30% to 50%.[4,64] Ganciclovir plus CMVIG also is considered effective for treatment of CMV disease, although this regimen has not been studied as extensively in the HCT population in a controlled fashion. However, CMVIG was not more effective than IVIG, therefore ganciclovir plus IVIG is considered as the treatment regimen of choice for severe or life-threatening CMV disease based on benefit-versus-risk considerations rather than definitive clinical data.[4,55,64] The potential for ganciclovir-associated bone marrow suppression prior to marrow engraftment and in patients who are just recovering from granulocytopenia remains a concern, especially in patients with unstable renal function. CSFs are beneficial in this setting (Table 145-7), providing benefits similar to those noted in patients with neutropenia and acquired immunodeficiency syndrome receiving ganciclovir therapy for CMV retinitis.[4]

Fungal Infections

Prophylaxis with antifungal agents is efficacious and generally recommended for prevention of mucocutaneous and disseminated fungal infections in high-risk HCT recipients (Tables 140-2 and 140-9).[2,4] Patients specifically recommended for prophylaxis with fluconazole or an echinocandin include all allogeneic recipients and autologous transplant recipients with extensive mucositis.[2,4] Fluconazole remains the most commonly used agent; it is started on the day of transplantation and continued until resolution of neutropenia or, in allogeneic HCT, for at least 75 days after transplantation.[4] The variable activity of fluconazole against non-*albicans* species of *Candida* may be problematic in this population, as is lack of activity against *Aspergillus*.[4] Prophylaxis with fluconazole effectively reduced colonization, infection, and infection-related mortality due to *Candida* spp. in some HCT populations, but has not consistently reduced overall mortality or invasive infections such as aspergillosis in all types of HCT recipients.[4] Micafungin was more efficacious than fluconazole in the prevention of early-onset *Candida* infections in HCT recipients with neutropenia prior to engraftment, and also showed a trend to fewer episodes of invasive aspergillosis.[4] Posaconazole was also more effective than fluconazole in the late prevention of invasive *Aspergillus* and other fungal infections in HCT recipients with GVHD receiving additional immunosuppressive therapy.[4] In a meta-analysis, prophylaxis with agents active against *Aspergillus* were associated with a 33% reduction in mortality related to invasive fungal infections compared to fluconazole.[37] Fluconazole and micafungin are both supported by a high level of evidence for fungal prophylaxis and either are appropriate following HCT with local fungal ecology, risk factors, and cost being appropriate determinants for specific populations.[4] Most experts consider caspofungin and anidulafungin reasonable alternatives to micafungin and current guidelines do not differentiate among echinocandins.[4] Voriconazole, posaconazole, LAMB products, and to a lesser extent itraconazole may be used for prophylaxis of fungal infections in HCT recipients but do not carry the same strength of recommendation due to less favorable side-effect profiles or lack of positive comparative studies.[4] Posaconazole is the preferred agent in high-risk HCT recipients with severe GVHD due to the risk of invasive mold infections (Table 145-2).[2,4] When the risk of invasive aspergillosis infection is >6%, prophylaxis with a mold-active triazole such as posaconazole (voriconazole or isavuconazonium as alternatives) is appropriate.[2] Isavuconazonium has not been well studied for prophylaxis in HCT recipients and, although recommended as an option in some clinical guidelines, it has not been recommended in others.[2,4]

Therapeutic drug monitoring for some azole antifungals remains important (Table 145-6). Furthermore, use of azole antifungals as prophylaxis introduces the potential for pharmacokinetic (CYP450 inhibition) and pharmacodynamic (eg, QTc prolongation with most azoles and fluoroquinolones) drug-drug interactions that vary in duration and severity. Drug half-lives, potential therapeutic benefit (eg, infection-free mortality), potential harm, and future oncologic plans must be assessed when initiating, continuing, adjusting, or discontinuing a potentially interacting medication. An alternative prophylaxis regimen (echinocandin) may be preferred to an azole when the risk of a drug interaction is too great (eg, proteasome inhibitors, tyrosine kinase inhibitors, or vinca alkaloids). Consideration should be given to the mechanism of drug interaction and drug half-life before initiating therapy.[4]

Pulmonary infection with *P. jirovecii* is a relatively infrequent complication of HCT that is associated with high rates of mortality, especially in patients with GVHD.[4,50,54] Therefore, prophylaxis is recommended for a period of 3 to 6 months after autologous HCT, and for at least 6 months and while receiving immunosuppressive therapy after allogeneic HCT. Exposure to specific immunosuppressing medications (eg, >20 mg of prednisone daily for >4 weeks) also warrants prophylaxis. Prophylaxis with trimethoprim–sulfamethoxazole significantly reduces the incidence of *P. jirovecii* as well as *P. jirovecii*-related mortality so effectively that desensitization should be considered for intolerant reactions before switching to an alternative (eg, dapsone, atovaquone, or pentamidine).[4,44,54] Trimethoprim–sulfamethoxazole should also prevent *Toxoplasma gondii*, a rare but often fatal infection.[4,54]

Use of Colony-Stimulating Factors

Filgrastim, pegfilgrastim, and sargramostim have been studied in HCT recipients in an effort to speed bone marrow recovery, reduce the period of neutropenia, and decrease infectious complications. CSFs appear effective as well as safe following autologous HCT and should be utilized. Although increased rates of GVHD and mortality with use of CSFs following allogeneic HCT have been reported by retrospective studies, a meta-analysis found no increased risk and CSFs may be given to allogeneic HCT recipients to reduce the duration of severe neutropenia.[41] The use of CSFs is now routinely recommended to mobilize blood progenitor cells and reduce the period of neutropenia in autologous transplants (Table 145-7).[33,41,42]

Evaluation of Therapeutic Outcomes

⑩ Close monitoring of HCT recipients, including clinical and laboratory data, is essential for early detection and treatment of infectious complications. In addition, because many of the drugs commonly used in this setting (eg, ganciclovir, amphotericin B, and trimethoprim–sulfamethoxazole) have significant toxicity potential in HCT recipients, careful attention must be paid to prevention and management of drug-related adverse effects as well as drug-drug interactions. Monitoring parameters related to specific types of infections (eg, pneumonia and urinary tract infections) should be applied as appropriate. The reader is referred to other chapters within this book for more specific information.

INFECTIONS IN SOLID-ORGAN TRANSPLANT RECIPIENTS

Solid-organ transplantation (SOT) is an established mode of treatment for end-stage diseases of the heart, lungs, kidney, liver, pancreas, and small bowel. More than 39,000 organs were transplanted in the United States in 2020, and nearly 900,000 organs have been transplanted in the United States since 1988.[55] Patient and allograft survival rates have greatly improved due to improvements in immunosuppressive drug therapy, candidate selection, and transplant surgery techniques as well as more experience in the management of complications (including infection) in these patients. Despite advances in diagnostic techniques and antimicrobial therapy, infectious complications remain important causes of morbidity and mortality after SOT.

Risk Factors

① Many risk factors for infection are present in SOT recipients (see Table 145-1). The most important risk factor in this population is immunosuppressive drug therapy for prevention and treatment of allograft rejection. Risk of infection depends on specific immunosuppressive drug regimens as well as the intensity (numbers and doses/exposure of drugs) and duration of immunosuppression. Most opportunistic infections in transplant patients occur during the first 6 months after transplantation, when the intensity and total cumulative exposures to immunosuppressive therapy are very high.[56,57,65,66]

Immunosuppressive drugs, often in escalated doses, are used to treat episodes of graft rejection and include immunoglobulins directed against T cells (eg, antithymocyte globulin), antibodies against interleukin 2 receptors (basiliximab), T-cell–depleting antibodies (alemtuzumab), B-lymphocyte depleting antibodies (rituximab), and high-dose corticosteroids. Rejection episodes often occur during the period 2 to 4 months posttransplant when the overall cumulative dose or net state of immunosuppression is high. Therefore, patients already at risk for infection are placed at even higher risk if additional immunosuppressive therapy is needed to treat one or more episodes of graft rejection.[65,67] Immunosuppressive drug therapy must be evaluated carefully when infections occur because, in many cases, immunosuppression may have to be reduced or altered to allow patients to survive the infectious episode, at the expense of increased risk of graft rejection. Risk of increased infectious complications from immunosuppressive therapy used to treat rejection episodes is determined, at least in part, by the specific therapy used.[56,65,68]

The organ type, organ donor status, surgical technique, recipient status, and underlying illness of the recipients are also critical determinants of infection risk and possible etiologies. These considerations are extremely important within the first 3 months following SOT and may provide heightened suspicion leading to specific prophylaxis, preemptive strategies, and earlier appropriate and targeted treatment of infectious complications.[58,59,67–69]

Etiology

② As in patients with cancer, microorganisms infecting SOT recipients are present before transplantation or are acquired from exogenous sources. Although opportunistic viral, fungal, and protozoal infections may occur commonly, bacterial infections remain the most frequent infectious complications after transplantation in all allograft recipients.[65,70,71] Liver, small bowel, and lung transplant recipients are at high risk for serious gram-negative bacterial infections as a result of the technically difficult surgical procedures and precolonization.[70,72] All transplant recipients are at risk for mucocutaneous candidiasis from species colonizing body sites. Invasive fungal infection is less common following kidney and pancreas transplantation but may occur in up to 30% to 60% of heart, lung, liver, and small bowel transplant recipients. Invasive fungal infections following lung, liver, and small bowel transplantation are associated with mortality rates up to 60% to 80%.[73,74] *Candida* spp. is the most common of all systemic fungal infections in transplant recipients.[74–76] Abdominal surgery, especially the more complex procedures required for liver and small bowel transplantation, predispose patients to serious fungal disease, most likely as a consequence of entering an area of the body already colonized with *Candida* spp.[64] Lung and heart transplant recipients are particularly at risk for invasive aspergillosis; these infections may occur in up to 35% of patients and in lung transplant recipients may be more common than infections caused by *Candida* spp.[63,64,73,77]

Organisms present as latent tissue infections may reactivate and cause clinical disease with administration of immunosuppressive drug therapy. Disease resulting from infection reactivation has been noted with viruses (HSV, human herpesvirus-6, CMV, VZV, Epstein–Barr virus [EBV]), protozoa (*T. gondii*), and mycobacteria (*Mycobacterium tuberculosis*).[65–68] Serologic or immunologic tests are performed prior to transplantation to assess the risk for reactivation infection and identify other subclinical infections (eg, HBV, hepatitis C virus [HCV], *Legionella*). Many patients with reactivated infection have no clinical symptoms; often the only evidence of active infection is a rise in antibody titer from the pretransplant baseline, positive culture, increasing viral replication, or histologic evidence. Reactivation of latent infection may result in severe life-threatening disease in immunosuppressed hosts.[56,58,66,67]

Exogenous sources of infection in transplant patients include environmental contamination and transmission of microorganisms via transplanted organs and blood products. Environmental sources of infection are similar to those noted in other immunocompromised hosts, such as patients with cancer. Airborne pathogens, especially fungi such as *Aspergillus* and *Cryptococcus neoformans*, may cause infections in transplant patients; environmental exposure is an established risk factor for invasive mold infections among lung transplant patients.[63] Travel to areas of geographically endemic mycoses (eg, *Coccidioides immitis*, *Histoplasma capsulatum*, *Blastomyces dermatitidis*) or animal exposures may broaden infectious risk.[56] SOT recipients are also at high risk for nosocomial infections (MRSA, *P. aeruginosa*, *Acinetobacter*). Optimal prevention and management of nosocomial infections in transplant patients require knowledge of the current epidemiology of infections and susceptibility patterns within an institution.[56,57,60,61]

Infections transmitted via donor organs or blood products are major causes of morbidity and mortality in transplant patients and may include HSV, *T. gondii*, HBV, and HCV. The most important infections transmitted from the donor, however, are caused by CMV.[67–69] These infections may cause serious disease, and predispose patients to other opportunistic infections, and contribute to acute and chronic allograft dysfunction or rejection, post-transplant lymphoproliferative disorders (particularly associated with EBV), and cardiac complications and atherosclerosis in heart transplant recipients.[67–69] In contrast to reactivation disease, transplant patients contracting primary CMV disease are at increased risk for serious life-threatening infections.[56,58,67–69] The most important source of primary CMV infection in transplant patients is the donor organ. Efforts are made to avoid transplanting organs from CMV-seropositive donors into CMV-seronegative recipients because of the potentially severe consequences. With the relative scarcity of suitable organs and the rapidity with which transplant decisions often must be made, however, this is not always possible. The consequences of transplanting an organ from a CMV-seropositive donor into an already CMV-seropositive recipient are less clear. CMV reinfection (as well as reactivation) syndromes may occur in these patients and antilymphocyte immunosuppression may increase the risk of complications.[56,59,67,69] Conversely, mammalian target of rapamycin (mTOR) inhibitors as part of a chronic immunosuppressive regimen may decrease the risk of CMV infection and related disease.[67,69] CMV serostatus, net immunosuppression, and organ type (among others factors) inform the practitioner of risk to determine an appropriate preventative strategy.[56,59,67,69] Furthermore, primary CMV disease may be transmitted from seropositive blood products. The availability of leukoreduced and CMV-seronegative blood products has decreased the risk of transmission but has not eliminated it.

Organs from donors seropositive for *T. gondii* or HSV generally are not withheld from seronegative patients as effective prophylaxis is common. Organs from known HIV-infected donors may now be used for transplantation in HIV-infected recipients (the HIV Organ Policy Equity Act) and outcomes of a limited number of transplanted patients have been favorable thus far.[70] Center-specific and HIV-specific criteria often apply, but in general those stable on antiretroviral therapy with well-controlled disease may be considered for SOT (as well as HCT) without prohibitively high risk for acceleration of HIV disease or opportunistic infections beyond what would be expected in other transplant recipients. The impact of protease inhibitors and highly active antiretroviral therapy on long-term outcome of HIV-infected patients following transplantation is believed to have improved the overall feasibility of transplanting these individuals.[70,71] Similarly, with highly effective therapies now available, organs from HCV-infected donors may be used for transplantation in HCV-infected recipients (and in some cases HCV-negative recipients).[70,72]

Timing of Infections After Transplantation

As with HCT, the overall time course for infections can be divided into three general periods after transplantation (see Fig. 145-3).[56,57] Although risk of infection with specific pathogens varies with the type of transplant, the time course of infections is similar in all transplant recipients. During the early post-transplant period (within the first month after transplantation), patients are at risk for infections already present and brought forward from the pretransplant period (eg, HBV, HCV, HIV); postoperative infections, such as surgical wound and catheter infections; infection resulting from colonized donor organs (pneumonia following lung transplant); and reactivation of HSV.[56,57,67] In the intermediate post-transplant period (1-6 months after transplant), risk is highest for viral infections, including CMV, EBV, HBV, and HCV. The combination of these "immunomodulating" viruses plus sustained immunosuppressive therapy leads to a high risk for opportunistic infections with pathogens such as *P. jirovecii*, *Aspergillus*, and *Nocardia asteroides*.[56–58] In the late post-transplant period (greater than 6 months after transplant), patients are at risk for persistent infections (particularly viral) from earlier post-transplant periods, reactivation of VZV and *Cryptococcus neoformans*, and routine infections affecting the general population.[56,57] In addition, patients who required additional immunosuppression therapy for acute or chronic rejection are at continued high risk for opportunistic infections (*Aspergillus* and *P. jirovecii*).[56,57] Although Fig. 145-3 illustrates infection patterns common to all solid-organ transplants, the relative incidence and importance of a particular pathogen vary according to the type of transplant, immunosuppression, and prophylaxis measures.

Types of Infections and Clinical Presentation

⑩ Transplant patients are at risk for infections occurring at a variety of sites, including skin, surgical wound, urinary tract, lungs, blood, abdomen, and CNS. However, most infections occur at or near the site of the transplanted organ. For example, heart transplant and heart-lung transplant recipients most often are infected within the lungs or thoracic cavity. Urinary tract infections remain an important cause of morbidity in renal transplant patients, especially in the early posttransplant period. Administration of prophylactic antibiotics (eg, trimethoprim–sulfamethoxazole) to these patients has reduced the incidence and severity of urinary tract infections.[4,69] Serious bacterial and fungal infections originating from the abdomen and GI tract are most common after liver transplantation and are related to variables such as length of surgery and surgical procedures performed. Risk of bacteremia, usually originating from the gut, is high in liver transplant patients. Renal transplant recipients are at the lowest risk for infections and infectious deaths, whereas patients receiving heart, lung, and liver transplants are at the highest risk for infection-related morbidity and mortality.[61,73]

In contrast to patients with febrile neutropenia, the threshold for initiating empirical antimicrobial therapy is higher in febrile transplant patients. Appropriate therapy for the large numbers of pathogens that may cause infections in transplant patients varies greatly from organism to organism (Table 145-6). Therefore, careful attempts at definitive diagnosis of suspected infections must be made. If comprehensive workup reveals no source of infection, careful observation of the febrile transplant patient (rather than empirical therapy) is common practice. Surveillance cultures and specifically weekly quantitative amplification nucleic acid testing of CMV may be useful during the first 3 to 4 months for detecting CMV infections if the patient is not receiving prophylaxis.[56,67,69] Management and monitoring of documented infections are similar to that in other types of patients.

CLINICAL PRESENTATION

CLINICAL PRESENTATION: Infections in Solid-organ Transplant Patients

General

- Because transplant patients are at high risk for serious infections, frequent (at least daily), careful clinical assessments must be performed to search for evidence of infection
- Clinical presentation of infection is variable and depends on the type and site of infection, type of transplant, time after transplantation, immune status of the host, and dose and duration of immunosuppressive therapy
- Primary viral disease usually is more symptomatic and severe than disease caused by reactivation
- Physical assessment should include examination of all common sites of infection, including mouth/pharynx, nose and sinuses, respiratory tract, GI tract, urinary tract, skin, soft tissues, perineum, and intravascular catheter insertion sites

Symptoms

- Usual signs and symptoms of infection may be absent or altered in patients receiving intensive immunosuppressive regimens owing to an inability to mount a typical inflammatory response (eg, no infiltrate on chest x-ray film, urinary tract infection without pyuria)
- Pain may be present at infection site(s)

Signs

- Fever is the single most important clinical sign indicating the presence of infection, though it may not be present in all infected patients. Other causes of fever unrelated to infection in this patient population include reactions to blood products, drugs, embolic events, and ischemic injury
- Usual signs of infection may be absent or altered
- Signs of allograft dysfunction may be related to infection. Distinguishing fever caused by allograft rejection from that caused by infection often is difficult and frequently requires allograft biopsy

Laboratory Tests

- Blood cultures (at least two sets, including vascular access devices) for bacteria and fungi; cultures of other suspected or potential infection sites (urine, lungs, surgical wounds, and soft tissue infections)
- Other cultures should be obtained as clinically indicated according to the presence of signs or symptoms
- Complete blood count and chemistries should be obtained frequently to monitor allograft function, plan supportive care, guide drug dosing, and assess patient’s overall status
- Surveillance testing for CMV and HSV may be useful during first 3 months after transplantation for early detection of infection

Other Diagnostic Tests

- Chest x-ray film
- Aspiration, biopsy of skin lesions
- Other diagnostic tests as indicated clinically on the basis of physical examination and other assessments

PREVENTION AND TREATMENT

Desired Outcomes

The goals of therapy in managing SOT recipients are similar to those in HCT and include : (a) protect the patient from early death caused by undiagnosed infection, from the surgical procedure through the late postengraftment period; (b) prevent common bacterial, fungal, viral, and protozoal/parasitic infections; (c) effectively and aggressively treat established infections; (d) avoid unnecessary use of antimicrobials; and (e) minimize toxicities and cost while increasing patient quality of life and avoiding harm to the engrafted organ(s).

Prevention of Infection in Solid-Organ Transplantation

⑧ The goals of antimicrobial drug use in solid-organ transplant recipients are (a) prevention of infectious complications in the immediate postoperative period, (b) prevention of late infectious complications associated with prolonged periods of immunosuppression, and (c) effective treatment of established infections in order to prevent graft dysfunction and rejection and decrease patient morbidity and mortality. All of these goals must be achieved at the lowest possible toxicity and cost.

Prevention of infection in the transplant patient can be accomplished in several ways. First, risk of environmental contamination should be minimized.[56] Patients should be protected from institutional infectious outbreaks. Efforts should be made to vaccinate organ transplant candidates prior to transplantation whenever possible for vaccine preventable disease based on age and anticipated risk factors post-transplant. Live vaccines should be given more than 4 weeks in advance from the time of anticipated transplantation.[48] Transplant recipients should receive influenza vaccination annually, pneumococcal (PCV13 and/or PPSV23 separated by 8 weeks), hepatitis A and B vaccination series (if indicated, ideally started pretransplant), HPV series (if indicated), zoster series, and Tdap generally 2 months or greater following transplantation; however, their immunologic responses to these vaccines may be suboptimal due to immunosuppressive therapy.[48] Timing of reinstitution of regular vaccinations in relation to transplantation is not absolute, but live-attenuated vaccines (varicella, zoster, MMR) should be avoided early post transplantation, if not altogether, similar to recommendations for HCT.[48] An exception is made for varicella seronegative pediatric liver and kidney transplant recipients who are on low levels of immunosuppression without recent graft rejection.[48]

Because the most important source of primary CMV infection is an infected donor organ, CMV serostatus should be evaluated in all recipients and donors. Two standard strategies to manage CMV in SOT recipients have been recommended. Preemptive therapy is effective for some populations (eg, kidney transplant) but requires weekly monitoring, close follow-up and appropriate risk stratification of patients for CMV related complications. Prophylaxis is effective and easy to administer without the need for careful discrimination of suitable patients; but, universal prophylaxis results in unnecessary exposure (toxicities) and cost to low-risk patients (CMV serostatus donor negative, recipient negative).[67,69] The best approach to preventing CMV disease remains controversial and does require risk stratification as either preemptive therapy or prophylaxis can be appropriate depending on patient specific factors (including immunosuppressive strategy). Most experts agree that CMV prophylaxis is not required in donor negative, recipient negative SOT patients. These patients may qualify for antiviral prophylaxis targeted against other herpes infections (eg, acyclovir) or preemptive therapy.[56,60,69]

CMV prophylaxis is commonly recommended in high-risk patients (ie, seronegative patients receiving seropositive organs). Oral valganciclovir and IV ganciclovir prophylaxis are effective for reducing the incidence of both primary and reactivated CMV infection in SOT.[67,69] Prophylaxis is recommended as a preferred strategy in many CMV-seropositive SOT recipients partly due to a lack of well-designed studies comparing prophylaxis to preemptive therapy in all SOT types.[67,69] Additional risk factors for CMV disease, the associated clinical impact of “indirect effects” of CMV, and logistical barriers should be considered on an individual basis when designing a strategy. For example, valganciclovir prophylaxis has been recommended for all CMV positive lung transplant recipients in part due to very high risk of CMV disease and associated severe consequences of direct and indirect effects on the graft.[56,69] The duration of CMV prophylaxis is typically 3 to 12 months depending on donor and recipient CMV serology status, immunosuppressive regimen, and type of organ transplanted.[56,67,69] Because CMV replication and disease occurs in up to one-third of donor-positive/recipient-negative SOT recipients within 3 to 6 months after stopping prophylaxis (termed postprophylaxis delayed-onset CMV disease), continued surveillance after discontinuation of prophylaxis should be considered based on patient-specific risk stratification.[56,67,69] Ganciclovir or valganciclovir prophylaxis also may significantly reduce reactivation of CMV infection in seropositive patients receiving antithymocyte globulin for treatment of acute rejection.[67,69]

Prophylactic high-dose oral acyclovir or valacyclovir effectively reduces the incidence of CMV infection and disease following renal transplantation. However, acyclovir is less active against CMV and may be less efficacious in some high-risk renal or other nonrenal transplant patients; therefore, valganciclovir is generally preferred if prophylaxis is required.[56,67,69] Acyclovir prophylaxis may be recommended for targeting other herpes viruses when the risk of CMV is low and should not be used to treat active CMV replication.[69,74]

Preemptive IV ganciclovir or valganciclovir is an effective strategy in many SOT recipients, but requires appropriate monitoring and a reliance on patient compliance. Additionally, no established thresholds have been clearly defined as a "cut-point" for initiation of preemptive valganciclovir when monitoring quantitative CMV copies (eg, absolute value, viral load kinetics, or viral doubling time).[67,69] Neither preemptive nor prophylaxis strategies are perfect for each situation. Therefore it is imperative that each SOT center develop a method based on patient risk, logistics, and cost and continually assess patient risk with cumulative net immunosuppression in mind when prescribing a CMV preventative strategy.[67,69] Since ganciclovir-related bone marrow suppression is not as problematic in SOT recipients as in HCT recipients and valganciclovir is relatively well tolerated, many centers in the United States opt for a prophylactic strategy extending either duration or preemptive monitoring when additional risk factors (eg, intensified immunosuppression) are encountered.

The additional benefit of CMVIG compared to standard CMV prophylaxis in high risk heart, lung, and small bowel transplant recipients is controversial. Cohort-level evidence suggests some possible benefit and therefore some experts will add monthly infusions in special circumstances; however, the optimal role of CMVIG has yet to be established.[56,67,69]

The use of mTOR inhibitors (sirolimus, everolimus) as part of an immunosuppressive regimen in SOT recipients may be useful in prevention of CMV disease. mTOR inhibitors exert a marked anti-CMV effect through reduction in viral replication and/or potent immunomodulating properties.[75] In a meta-analysis, patients receiving immunosuppressant regimens containing mTOR inhibitors (with or without a calcineurin inhibitor [CNI]) displayed a nearly three-fold reduction in CMV infections compared to patients receiving CNI alone.[75] Although mTOR inhibitors are associated with significantly lower CMV infection rates in most SOT recipients, CMV disease with related complication is only one of many factors that must be considered when designing an immunosuppressive regimen.[67,69]

Although use of prophylactic acyclovir in HSV-seropositive patients undergoing HCT is well accepted, prophylaxis in SOT recipients remains controversial. Reactivation disease caused by HSV occurs in approximately 25% of HSV-seropositive patients who are not receiving prophylaxis.[74] Mucocutaneous disease is the most common presentation, but nonmucocutantious HSV disease also is seen occasionally and is associated with significant morbidity and high mortality (eg, HSV pneumonitis).[74] Acyclovir is therefore used at some centers because of the high incidence of clinical HSV infection after transplantation. Acyclovir prophylaxis of HSV infection may be considered in patients following a preemptive strategy for management of CMV infection, but would not be necessary in patients receiving ganciclovir or valganciclovir for CMV prophylaxis.[56,74]

Prophylactic antimicrobial agents are also of benefit to SOT recipients in certain other clinical situations. Antibiotic prophylaxis, with agents such as cefazolin started perioperatively and continued for less than 24 hours, is considered to effectively reduce wound infection rates following renal transplantation.[62,73] Although the benefits of perioperative prophylaxis have not been well studied in other types of transplantation procedures, surgical prophylaxis usually is considered mandatory for pancreas, liver, heart, lung, or small bowel transplant patients because of the high risk of perioperative bacterial infections.[62,73] High rates of infection have been reported following liver and intestinal transplant often resulting from intra-abdominal pathogens (eg, gram-negative bacteria, *Enterococcus*, *Candida*, anaerobes) depending on patient, donor, and surgical risk factors. Broader surgical prophylaxis such as a third-generation cephalosporin plus ampicillin, ampicillin/sulbactam, or piperacillin/tazobactam have been recommended for liver transplant. An even broader approach with the addition of vancomycin and fluconazole has been suggested for intestinal transplant given the high risk of multidrug resistant and polymicrobial infection.[62] Pulmonary infections are particularly common in lung and heart-lung transplant recipients. They often are caused by bacteria colonizing the airways of the diseased organs prior to transplantation. Therefore, perioperative antibiotics for lung and heart-lung procedures often are selected based on pretransplant sputum cultures and/or known colonizations of the patient (including assist devices [eg, ventricular assist device or extracorporeal membrane oxygenation circuit]).[62]

Post-transplant antibiotic prophylaxis is effective in decreasing the number of bacterial infections in renal transplant patients. Prophylactic trimethoprim–sulfamethoxazole traditionally has been used because it is inexpensive and well tolerated; other antibiotics, such as the fluoroquinolones, also have been evaluated.[56] Administration of oral low-dose trimethoprim–sulfamethoxazole (one double-strength tablet, either daily or three times/week) for 6 to 12 months for prevention of *P. jirovecii* infection following heart and lung transplantation is common, although the efficacy and optimal duration are somewhat controversial.[56] Selective bowel decontamination with nonabsorbable antibiotics in combination with a low-bacterial diet (no fresh fruits and vegetables) may reduce oropharyngeal and GI colonization with gram-negative aerobes and *Candida* in liver transplant patients; however, conclusive evidence of benefit is lacking and this practice is not recommended routinely.[62,73] Similarly, prebiotics and probiotics cannot be currently recommended.[62]

Because immunosuppressed transplant recipients are at risk for mucocutaneous fungal infections, prophylactic oral or topical antifungal agents may be indicated in these patients. Liver, pancreas, and small bowel transplant recipients are clearly at high risk for invasive fungal infections and should receive prophylaxis with fluconazole though the optimal duration remains unclear.[62,66] Antifungal prophylaxis has also been suggested for lung and heart-lung transplant recipients due to the high incidence of invasive fungal infections in these patients (up to 35% of patients, with mortality rates up to 60%).[64] Prophylaxis targeting *Aspergillus* spp. with inhaled amphotericin B or LAMB, or systemic regimens active against *Candida* and *Aspergillus* spp. such as itraconazole, voriconazole, posaconazole, and echinocandins have all been reported; however, data from well-designed trials supporting either the general recommendation for prophylaxis or choice of specific agent are largely lacking and center-to-center variability is great.[63,65,74] Oral voriconazole or inhaled LAMB for a period of 3 to 6 months post-transplant are most often recommended for prophylaxis of invasive fungal infection in lung and heart-lung transplant recipients.[63,64] However, prophylaxis out to a year or longer is not uncommon with oral triazole agents.[63,64] Concentrations of immunosuppressant drugs should be monitored closely in transplant patients receiving azole-type antifungal agents (fluconazole, itraconazole, and voriconazole).

Transplant patients, especially heart and heart-lung recipients, without serologic evidence of prior exposure to *T. gondii* who receive organs from seropositive donors are at high risk for toxoplasmosis.[56] Many of these patients will be receiving trimethoprim–sulfamethoxazole for prophylaxis of *P. jirovecii* infection; this agent will also provide effective prophylaxis against *T. gondii* as well as *N. asteroides*. Although prophylaxis specifically for *T. gondii* is not given routinely at all centers, this therapy for a period of up to 12 months may be justified in high-risk patients because of the delays in diagnosis and serious infections associated with toxoplasmosis.[56,71]

SELF-ASSESSMENT QUESTIONS

1. What is the most important risk factor for development of severe infections in cancer patients?
   - A. Alteration of normal flora by chemotherapy and antimicrobial therapy
   - B. Prolonged neutropenia
   - C. Severe mucositis
   - D. Humoral and cellular immune system defects
2. The most common bacterial microorganism(s) causing infections in neutropenic cancer patients is/are:
   - A. *Klebsiella pneumonia* and *Escherichia coli*
   - B. *Pseudomonas aeruginosa*
   - C. Staphylococci and streptococci
   - D. *Clostridium* species
3. All of the following are appropriate antibiotic de-escalation strategies for antimicrobial coverage after a period of febrile neutropenia, except:
   - A. Antibiotics can be discontinued after an appropriate duration for the isolated organism and site, provided neutropenia has resolved
   - B. In low-risk patients, empiric therapy can be de-escalated to an oral regimen after 2 days of intravenous therapy provided the patient is now afebrile and has no evidence of infection
   - C. In high-risk patients, empiric therapy should be de-escalated to narrow spectrum agents once an organism is isolated to prevent antibiotic resistance
   - D. All of the above are appropriate antibiotic de-escalation strategies
4. Which of the following antibiotic regimens is preferred for the initial management of an episode of febrile neutropenia in a hemodynamically stable patient with a MASCC score <21?

   A. Intravenous piperacillin/tazobactam

   B. Intravenous cefepime plus ciprofloxacin

   C. Intravenous meropenem plus vancomycin

   D. Intravenous ceftaroline

5. Which of the following statements regarding initial empiric vancomycin therapy in febrile neutropenic patients with cancer is false?

   A. All initial empiric regimens should contain vancomycin.

   B. Patients with evidence of IV catheter infections may benefit from initial empiric therapy with vancomycin.

   C. Decreased mortality from penicillin-resistant viridans streptococcal infections has been observed with initial empiric vancomycin therapy.

   D. If empiric vancomycin therapy is initiated and no evidence of gram-positive infection is found after 24 to 48 hours, vancomycin should be discontinued.

6. All of the following antimicrobials are reasonable options for prophylaxis of infections in a HCT recipient expected to be profoundly neutropenic for >7 days, except:

   A. Levofloxacin

   B. Posaconazole

   C. Acyclovir

   D. Aztreonam

7. Which of the following antibiotic regimens is/are preferred for managing episodes of febrile neutropenia in low-risk patients?

   A. Ciprofloxacin plus amoxicillin/clavulanate

   B. Vancomycin plus levofloxacin

   C. Ciprofloxacin plus clindamycin

   D. Metronidazole plus moxifloxacin

8. All of the following infections would be anticipated during the immediate period (within approximately 1 month) after lung transplantation, except:

   A. Surgical wound infections

   B. Pneumonia

   C. Cytomegalovirus (CMV) disease in a patient who was CMV-seronegative before transplantation

   D. Reactivation of herpes simplex virus (HSV) infection in a patient who was HSV-seropositive before transplantation

9. Patients undergoing hematopoietic cell transplantation are at significant risk for infection in all of the following scenarios, except:

   A. Primary or recurrent Varicella Zoster Virus infection in a patient with graft-versus-host disease

   B. Cytomegalovirus (CMV) infection in a CMV-seronegative recipient receiving stem cell donations from a CMV-seropositive donor

   C. *Candida* or *Aspergillus* infections in patients receiving allogeneic hematopoietic cell transplants

D. All of the above are scenarios in which patients are at high risk of infection

10. Compared to monotherapy, which of the following is true regarding the use of empiric dual-gram-negative coverage for high-risk febrile neutropenic patients:

A. Dual therapy is associated with a greater risk of drug-related adverse effects

B. Dual therapy is associated with a greater risk of breakthrough resistant infections

C. Dual therapy is associated with a lower risk of 30-day mortality

D. Dual therapy is associated with a lower risk of secondary fungal infections

11. Patients undergoing hematopoietic stem cell transplantation are routinely recommended to receive all of the following vaccinations within 2 years of transplant, except:

A. *Haemophilus influenzae* type B vaccine

B. Varicella vaccine

C. 23-valent pneumococcal vaccine

D. Influenza vaccine

12. Which of the following regimens would be most appropriate for prophylaxis of *Pneumocystis jirovecii* infection in a double-lung transplant recipient?

A. Trimethoprim–sulfamethoxazole two double-strength tablet orally twice daily

B. Trimethoprim–sulfamethoxazole one double-strength tablet orally once daily

C. Pentamidine 4 mg/kg intravenously once daily

D. Pentamidine 300 mg inhaled once monthly

13. Therapeutic drug monitoring is recommended during use of all of the following agents, except:

A. Voriconazole

B. Vancomycin

C. Posaconazole

D. Isavuconazonium

14. An appropriate regimen for the treatment of confirmed invasive pulmonary aspergillosis in a neutropenic cancer patient would be:

A. Fluconazole 800 mg intravenously × one dose, followed by 400 mg intravenously once daily

B. Liposomal amphotericin B 1 mg/kg intravenously once daily

C. Voriconazole 6 mg/kg intravenously twice daily × two doses, followed by 4 mg/kg intravenously twice daily

D. All of the above would be appropriate regimens for the stated patient

15. A 45-year-old female undergoes hematopoietic stem cell transplantation for advanced metastatic breast cancer and develops cytomegalovirus disease 2 months after transplantation. She is started on ganciclovir 5 mg/kg intravenously every 12 hours. The most important ganciclovir-related adverse effect that should be carefully monitored for in this patient would be:

A. Bone marrow suppression

B. Mucositis

C. Nephrotoxicity

D. Central nervous system toxicities

SELF-ASSESSMENT QUESTION-ANSWERS

1. **B.** Although the other listed factors are important, the duration of neutropenia is the most critical risk factor for the development of severe infections in cancer patients. See the Introduction ("Risk Factors for Infection/Epidemiology") section of the chapter for more information.

2. **C.** Although infection with many different bacterial pathogens are possible and/or relatively common, the majority of infections are caused by gram-positive bacteria including staphylococci and streptococci. See the "Etiology of Infections in Neutropenic Patients with Cancer" section of the chapter for more information.

3. **D.** All of the given options are potentially appropriate de-escalation strategies depending on laboratory results, clinical response to therapy, and continued risk factors for infection in individual patients, for example, continued neutropenia. See the Treatment ("Antimicrobial Therapy After Initiation of Empirical Therapy") section of the chapter for more information.

4. **A.** Patients with MASCC score <21 should be initially treated with broad-spectrum intravenous therapy that covers gram-negative bacteria (including *Pseudomonas aeruginosa*) as well as gram-positive bacteria. However, monotherapy is as effective as combination regimens for initial therapy and is preferred in most patients. See the Treatment ("Approach to Treatment") section of the chapter for more information.

5. **A.** Vancomycin may be included as part of the initial empiric antimicrobial regimen in carefully selected patients, but is not appropriate for all patients with neutropenic fever and should not be routinely used in all cases. See the Treatment ("Empirical Regimens Containing Vancomycin") section of the chapter for more information.

6. **D.** Prophylaxis with orally administered, systemically available antibiotics is effective at reducing gram-negative infections and is recommended for selected high-risk patients. Prophylaxis with antiviral and antifungal agents may also be appropriate in selected high-risk patients. See the Treatment ("Prophylaxis of Infections in Neutropenic Patients with Cancer") section of the chapter for more information.

7. **A.** Oral ciprofloxacin plus amoxicillin/clavulanate is the preferred antibiotic regimen for treatment of neutropenic fever in low-risk patients due to appropriate antibacterial coverage and favorable data from clinical studies. See the Treatment ("Oral Antibiotic Therapy for Management of Febrile Neutropenia") section of the chapter for more information.

8. **C.** Infections in the immediate post-transplant period typically involve infections at the site of the transplant, infections of the transplanted organ itself, or reactivation of existing infections. Cytomegalovirus-related disease typically occurs 1 to 6 months after transplantation. See the "Infections in Solid-Organ transplant Recipients" ("Timing of Infections After Transplantation") section of the chapter for more information.

9. **D.** Patients undergoing HCT are at high risk for a wide variety of infections due to prolonged periods of profound immunosuppression. These infections include reactivation of existing infections as well as diseases caused by acquisition of new bacterial, viral, and fungal pathogens. See the "Infections in Patients Undergoing HCT" ("Etiology and Clinical Presentation of Infections") section of the chapter for more information.

10. **A.** Dual, or combination, initial therapy of febrile neutropenia has not been proven to improve overall patients outcomes (eg, decreased mortality, decreased antibiotic resistance) but may result in increased rates of adverse drug effects compared to β-lactam monotherapy. See the Treatment ("Approach to Treatment") section of the chapter for more information.

11. **B.** VZV-seronegative patients undergoing HCT may be considered for receipt of the varicella vaccine to prevent primary infection. However, due to the live-virus nature of the product the varicella vaccine should generally not be administered within at least 24 months following transplantation. See the "Infections in Patients Undergoing HCT" ("Prophylaxis and Management of Infections in Recipients of HCT") section of the chapter for more information.

12. **B.** Trimethoprim–sulfamethoxazole administered once daily is the preferred regimen for prevention of *P. jirovecii* infections in transplant recipients. See the "Infections in Solid-Organ Transplant Recipients" ("Prevention of Infection in Solid-Organ Transplantation") section of the chapter for more information.

13. **D.** Therapeutic drug monitoring of isavuconazonium is not currently recommended due to lack of recommended target concentrations and unavailability of drug assays. See the Treatment ("Empirical Regimens Containing Vancomycin") and Treatment ("Initiation of Antifungal Therapy") sections of the chapter for more information.

14. **C.** Voriconazole is the preferred agent for initial therapy of invasive *Aspergillus* infections, including pulmonary aspergillosis, because of proven efficacy and fewer toxicities compared to amphotericin B products. See the Treatment ("Initiation of Antifungal Therapy") section of the chapter for more information.

15. **A.** Although considered the drug of choice for most patients with invasive CMV disease, ganciclovir's potential for myelosuppressive toxicity is an important consideration in patients who have undergone HCT. See the "Infections in Patients Undergoing HCT" ("Viral Infections") section of the chapter for more information.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e >

Chapter 146: Antimicrobial Prophylaxis in Surgery

Salmaan Kanji

KEY CONCEPTS

KEY CONCEPTS

①Prophylactic antibiotic therapy differs from presumptive and therapeutic antibiotic therapy, in that the latter involves treatment regimens for presumed or documented infections, whereas the goal of prophylactic therapy is to prevent infections in high-risk patients or procedures.

②The risk of a surgical site infection (SSI) is determined from both the type of surgery and the patient-specific risk factors; however, most commonly used classification systems account for only procedure-related risk factors.

③The timing of antimicrobial prophylaxis is of paramount importance. Antibiotics should be administered within 1 hour before surgery to ensure adequate drug levels at the surgical site prior to the initial incision.

④Antimicrobial agents with short half-lives (eg, cefazolin) may require intraoperative redosing during procedures that last more than 3 hours or 2.5 half-lives of the antimicrobial used.

⑤The type of surgery, intrinsic patient risk factors, most commonly identified pathogenic organisms, institutional antimicrobial resistance patterns, and cost must be considered when choosing an antimicrobial agent for prophylaxis.

⑥Single-dose prophylaxis is appropriate for many types of surgery. First-generation cephalosporins (eg, cefazolin) are the mainstay for prophylaxis in most surgical procedures because of their spectrum of activity, safety, and cost.

⑦Vancomycin as a prophylactic agent should be limited to patients with a documented history of life-threatening *β*-lactam hypersensitivity or those in whom the incidence of infections with organisms resistant to cefazolin (eg, methicillin-resistant *Staphylococcus aureus*) is documented or high enough to justify use.

BEYOND THE BOOK

BEYOND THE BOOK

Watch the video entitled “WHO: Prevention of surgical site infections (WHO Global Guidelines 2016)” at https://tinyurl.com/yyocdygz. In 2017, the World Health Organization (WHO) published global recommendations for the prevention of surgical site infections and produced this promotional video. After viewing the video, read the official press release at https://tinyurl.com/zttj3s9. These two media releases highlight the global impact of surgical site infections and the need for a world-wide approach to prevention.

INTRODUCTION

According to the National Center for Health Statistics and the National Hospital Discharge Survey, nearly 57 million outpatient and 51 million inpatient surgical procedures are performed annually in the United States.[1,2] Infection is the most common complication of surgery.[3] Surgical site infections (SSIs) occur in approximately 3% to 6% of patients and prolong hospitalization by an average of 7 days at a direct annual cost of $5 billion to $10 billion.[4,5] SSIs that involve a prosthetic joint or antimicrobial-resistant organism can cost in excess of $90,000.[6] SSIs are now the most common cause of nosocomial infections among hospitalized patients (20% of all hospital-acquired infections).[7] Incidence rates are likely under reported, as approximately 50% of SSIs occur after hospital discharge and the Centers for Disease Control and Prevention (CDC) defines SSI as an infection affecting the surgical incision or deep tissue at the operation site that occurs up to 30 days after surgery or even up to a year after surgery for patients receiving implants.[8] Prophylactic administration of antibiotics decreases the risk of infection after many surgical procedures and represents an important component of care for this population.

Antibiotics administered prior to the contamination of previously sterile tissues or fluids are called prophylactic antibiotics. The goal of prophylaxis is to prevent an infection from developing. Although eradication of distal (preexisting, unrelated to surgery) infections lowers the risk for subsequent postoperative infections, it does not per se constitute a prophylactic regimen. In fact, surgical prophylaxis should be prescribed concurrently under these circumstances because of important antimicrobial spectrum- and timing-related concerns. Both SSIs and hospital-acquired infections not directly related to the surgical site (eg, urinary tract infections and pneumonia) are termed *nosocomial*. Prevention of hospital-acquired infections is a major goal of antibiotic prophylaxis.

①Presumptive antibiotic therapy is administered when an infection is suspected but not yet proven. Clinical scenarios where presumptive therapy is used commonly include acute cholecystitis, open compound fractures, and acute appendicitis of less than 24-hour duration. In these situations, if signs of perforation, contamination, or infection are absent during surgery, then routine prophylactic treatment rather than presumptive therapy is warranted. An operative finding of a gangrenous gallbladder or a perforated appendix, however, is suggestive of an established infectious process, and a therapeutic antibiotic regimen is required.[4]

According to the CDC's National Nosocomial Infections Surveillance System (NNIS),[4,7] SSIs can be categorized as either incisional (eg, cellulitis of the incision site) or organ/space (eg, meningitis; Fig. 146-1). Incisional SSIs are subcategorized into superficial (involving only the skin or subcutaneous tissue) and deep (fascial and muscle layers) infections. Organ/space SSIs can involve any anatomic area other than the incision site. For example, a patient who develops bacterial peritonitis after bowel surgery has an organ/space SSI. Although microbiologic testing of surgical drainage material or sites may help to guide care, the specificity of a negative culture is poor and generally does not rule out an SSI.[4,7] Clinical signs or symptoms of SSI may include localized heat, erythema, swelling, fever, and purulent drainage from the wound.

RISK FACTORS FOR SURGICAL SITE INFECTIONS

②SSI incidence depends on both procedure- and patient-related factors. The risk for SSIs has been stratified by surgical procedure in a classification system developed by the National Research Council (NRC; Table 146-1). The NRC classification system proposes that the risk of an SSI depends on the microbiology of the surgical site, the presence of a preexisting infection, the likelihood of contaminating previously sterile tissue during surgery, and the events during and after surgery.[8,9] A patient's NRC procedure classification is the primary determinant of whether antibiotic prophylaxis is warranted. However, because a patient's NRC wound classification is influenced by surgical findings (eg, gangrenous gallbladder) and perioperative events (eg, major technique breaks), categorization generally occurs intraoperatively.[10] Colon surgery has the highest rates of SSI followed by gall bladder, cardiac, gynecologic, orthopedic, and spinal surgery. Minimally invasive approaches to surgery, when available, tend to be associated with lower rates of SSI when compared to traditional approaches to the same surgery.[8]

TABLE 146-1

National Research Council Wound Classification, Risk of Surgical Site Infection, and Indication for Antibiotics

	SSI Rate (%)			
Classification	Preoperative Antibiotics	No Preoperative Antibiotics	Criteria	Antibiotics
Clean	0.8	5.1	No acute inflammation or transection of GI, oropharyngeal, genitourinary, biliary, or respiratory tracts; elective case, no technique break	Not indicated unless high-risk procedure[a]
Clean–contaminated	1.3	10.1	Controlled opening of aforementioned tracts with minimal spillage/minor technique break; clean procedures performed emergently or with major technique breaks	Prophylactic antibiotics indicated
Contaminated	10.2	21.9	Acute, nonpurulent inflammation present; major spillage/technique break during clean–contaminated procedure	Prophylactic antibiotics indicated
Dirty	N/A	N/A	Obvious preexisting infection present (abscess, pus, or necrotic tissue present)	Therapeutic antibiotics required

N/A, not applicable; SSI, surgical site infection.

[a] High-risk procedures include implantation of prosthetic materials and other procedures where SSI is associated with high morbidity (see the text).

Data from References 5,8.

Inherent Patient Risk

The NRC classification system does not account for the influence of underlying patient risk factors for SSI development, instead categorizing the risks for SSIs simply based on a specific surgical procedure. Certain disease states and conditions (listed in Table 146-2) are known to increase SSI risk by either increasing the length or complexity of the surgery (eg, obesity) or reducing the immune response (eg, diabetes). Preexisting distal infections increase SSI rates and should be resolved prior to surgery whenever possible. Diabetic patients have an increased risk for SSIs, especially those with uncontrolled perioperative blood sugars where risk is doubled.[11] Preoperative smoking is an independent risk factor for SSI because of the deleterious effects of nicotine on wound healing. Preoperative immunosuppression, including corticosteroid use, may also increase infection risk. Patients coinfected with human immunodeficiency virus (HIV) and hepatitis C are at approximately double the risk of SSI as the general population.[12] Malnutrition is a well-described risk factor for postoperative complications, including SSI, impaired wound and colonic anastomosis healing, and prolonged hospital stay. Although enteral feeding during the perioperative period can reduce bacterial translocation by maintaining the integrity of the intestinal mucosa, nutritional supplementation does not decrease the incidence of infection.[13] Some patient-related risk factors are potentially modifiable (glycemic control, alcohol and smoking status, preoperative albumin, and obesity). These represent opportunities for optimization prior to elective surgical procedures.[7]

TABLE 146-2

Patient and Operation Characteristics That May Influence the Risk of Surgical Site Infection

Patient	Operation
Age	Duration of surgical scrub
Nutritional status (preoperative albumin <3.5 g/dL [35 g/L])	Preoperative skin preparation
Diabetes and preoperative glycemic control	Preoperative shaving
Smoking and alcohol use	Duration of operation
Obesity	Antimicrobial prophylaxis
Coexisting infections at distal body sites	Operating room ventilation
Colonization with resistant microorganisms Altered immune response Length of preoperative stay	Sterilization of instruments Implantation of prosthetic materials Surgical drains Surgical technique

Colonization of the nares with *S. aureus* is a well-described SSI risk factor.[4] A large multicenter study involving more than 38,000 patients undergoing more than 42,000 cardiac and orthopedic procedures showed that preoperative screening for carriers of *S. aureus* followed by intranasal mupirocin administration and chlorhexidine bathing for 5 days before surgery significantly reduced *S. aureus* SSI from 0.36% to 0.2%.[11] Although the absolute risk difference is small, this represents a 44% relative risk reduction.[8] The potential impact on patient outcomes and health resource utilization is large, given the number of surgeries performed annually. However, the logistics and cost of prescreening and treatment of colonized patients represent a challenge. Other factors shown to increase the risk of SSI are age, length of preoperative hospital stay, and obesity.[4]

Identifying SSI Risk

Two large epidemiologic studies have objectively quantified SSI risk based on specific patient- and procedure-related factors. The Study on the Efficacy of Nosocomial Infection Control (SENIC) analyzed more than 100,000 surgery cases to identify and validate risk factors for SSI.[14] Abdominal operations, operations lasting longer than 2 hours, contaminated or "dirty" procedures (as per NRC classification), and more than three underlying medical diagnoses each was associated with an increased incidence of SSI. When NRC classification was stratified by the number of SENIC risk factors present, SSI incidence varied by as much as a factor of 15 within the same NRC operative category (Table 146-3).[15]

TABLE 146-3

Surgical Site Infection Incidence (%) Stratified by NRC Wound Classification and SENIC Risk Factors[a]

Number of SENIC Risk Factors	Clean	Clean–Contaminated	Contaminated	Dirty
0	1.1	0.6	N/A	N/A
1	3.9	2.8	4.5	6.7
2	8.4	8.4	8.3	10.9
3	15.8	17.7	11.0	18.8
4	N/A	N/A	23.9	27.4

[a] Study on the Efficacy of Nosocomial Infection Control (SENIC) risk factors include abdominal operation, operations lasting >2 hours, contaminated or dirty procedures by National Research Council (NRC) classification, and more than three underlying medical diagnoses.

N/A, not applicable; NRC, National Research Council; SENIC, Study on the Efficacy of Nosocomial Infection Control.

Data from Reference 15.

In a subsequent analysis of more than 84,000 surgical cases, the NNIS attempted to simplify and refine the SENIC system by quantifying intrinsic patient risk using the American Society of Anesthesiologists' (ASA) preoperative assessment score (Table 146-4).[16,17] An ASA score greater than or equal to 3 was a strong predictor for the development of an SSI. Other factors associated with increased SSI incidence are contaminated or "dirty" operations (NRC criteria) and surgical procedures lasting longer than average. As in the SENIC study, the SSI rate was linked to the number of risk factors present and varied considerably within NRC class. The NNIS basic SSI risk index is composed of the following criteria: ASA score = 3, 4, or 5; wound class; and duration of surgery. Overall, for 34 of the 44 NNIS procedure categories, SSI rates increased proportionally with the number of risk factors present.[8] The SSI rate was generally lower when the procedure was done laparoscopically.

TABLE 146-4

American Society of Anesthesiologists' Physical Status Classification

Class	Description
1	Normal healthy patient
2	Mild systemic disease
3	Severe systemic disease that is not incapacitating
4	Incapacitating systemic disease that is a constant threat to life
5	Not expected to survive 24 hours with or without operation

Data from Reference 17.

While these tools are able to broadly predict SSI risk, a more individualized approach to quantifying a patient's risk of developing an SSI is possible using the Surgical Site Infection Risk Score (SSIRS) which is a validated scoring system that incorporates both patient- and procedure-related risk factors.[18] Although evidence-based recommendations for antimicrobial prophylaxis during surgery are best established using the results of randomized clinical trials, many studies have small sample sizes and do not stratify patients according to overall SSI risk. Future studies, particularly those involving clean procedures, should be stratified by SSI risk so that the subset of high-risk patients who might benefit the most from prophylaxis is clearly established.

BACTERIOLOGY

The most important consideration when choosing antibiotic prophylaxis is the bacteriology of the surgical site. Organisms involved in an SSI are acquired by one of two ways: endogenously (from the patient's own normal flora) or exogenously (from contamination during the surgical procedure). Based on the type and anatomic location of the procedure and the NRC classification (see Table 146-1), resident flora can be predicted and appropriate antibiotic choices made. According to NNIS data, *S. aureus,* coagulase-negative staphylococci, enterococci, *Escherichia coli*, and *Pseudomonas aeruginosa* are the pathogens most commonly isolated (Table 146-5).[16] With the widespread use of broad-spectrum antibiotics, however, *Candida* species and methicillin-resistant *Staphylococcus aureus* (MRSA) are becoming more prevalent.[16]

TABLE 146-5

Major Pathogens in Surgical Wound Infections

Pathogen	Percent of Infections[a]
Staphylococcus aureus	20
Coagulase-negative staphylococci	14
Enterococci	12
Escherichia coli	8
Pseudomonas aeruginosa	8
Enterobacter species	7
Proteus mirabilis	3
Klebsiella pneumoniae	3
Other *Streptococcus* species	3
Candida albicans	3
Group D streptococci	2
Other gram-positive aerobes	2
Bacteroides fragilis	2

[a] Data reported by the National Nosocomial Infections Surveillance System from January 1992 through June 2004.

Data from Reference 5.

Factors affecting the ability of an organism to induce an SSI depend on organism count, organism virulence, and host immunocompetency. Organisms in the commensal flora generally are not pathogenic. These organisms often serve the host as a form of protection against invasive organisms that otherwise would colonize the surgical site. Opportunistic organisms usually are kept in check by normal flora and rarely are problematic unless they are present in large numbers. The loss of normal flora through the use of broad-spectrum antibiotics can destabilize homeostasis, allowing pathogenic bacteria to proliferate and infection to occur.[5]

Normal flora translocated to a normally sterile tissue site or fluid during a surgical procedure can become pathogenic. For example, *S. aureus* or *Staphylococcus epidermidis* may be translocated from the surface of the skin to deeper tissues or *E. coli* from the colon to the peritoneal cavity, bloodstream, or urinary tract. Studies in animals and healthy volunteers have shown bacterial virulence to be an important determinant in the development of secondary infections.[19,20] Whereas more than one million *S. aureus* per square centimeter or gram of tissue are required to produce infection in animals, less than 100,000 *Streptococcus pyogenes* per square centimeter or gram of tissue are required at the same site.[20,21]

Impaired host defense reduces the number of bacteria required to establish an infection. A breach of normal host defenses through surgical intervention (eg, insertion of a prosthetic device) may enable organisms to cause infection. In addition, the loss of specific immune factors, such as complement activation, tissue-derived inhibitors (eg, proinflammatory cytokines), cell-mediated response (eg, T-cell function), and granulocytic or phagocytic function (eg, neutrophils or macrophages), can greatly increase the risk for SSI development.[22] Vascular occlusive states related to the surgical procedure or those occurring from hypovolemic shock can greatly affect blood flow to the surgical site, thus diminishing host defense mechanisms against microbial invasion. Traumatized tissue, hematomas, and the presence of foreign material also lead to more infections. When a foreign body is introduced during a surgical procedure, fewer than 100 bacterial colony-forming units are required to cause an SSI.[23] Studies examining *S. aureus*-contaminated wound infections on the skin of healthy volunteers demonstrate a 10,000-fold reduction in the number of organisms required to establish a wound infection if sutures are not present.[19]

ANTIMICROBIAL RESISTANCE AND STEWARDSHIP

Colonization of the host with antibiotic-resistant hospital flora prior to or during surgery may lead to an SSI that is unresponsive to routine antibiotic therapy. The most common cause of nosocomially acquired multiresistant organisms is transmission from hospital personnel.[24] Patients treated with broad-spectrum antibiotic therapy are at increased risk for colonization with hospital flora.

With cephalosporins established as first-line agents for prophylaxis, organisms resistant to cephalosporins represent the majority of pathogens causing SSIs. MRSA and coagulase-negative staphylococci have emerged as the most common pathogens in patients who develop SSIs despite prophylaxis with cephalosporins particularly in cardiothoracic, vascular, orthopedic, and neurologic surgery. Methicillin resistance not only limits the treatment/-prophylaxis options available, but it also is associated with increased mortality, longer hospital lengths of stay, and increased costs. Although the use of vancomycin for prophylaxis may be appropriate for some operations performed in hospitals with a high rate of infection due to MRSA, there is little guidance on what constitutes a “high rate” of MRSA infection and whether providing prophylaxis with vancomycin alone will result in fewer SSIs.[25] A more effective strategy would be to screen elective surgical candidates for MRSA colonization preoperatively. MRSA colonization is predictive of MRSA SSI and thus effective prophylaxis with vancomycin is then reserved for carriers only. Some single center studies evaluating the decolonization of MRSA carriers preoperatively (ie, with intranasal mupirocin, chlorhexidine showers) have yielded mixed results and may not be cost-effective.[25]

The increase in frequency of fungal infections in surgical patients has drawn concern. In hospitalized patients, the incidence of nosocomial *Candida* infections nearly doubled from 1992 to 2004.[16,26] Overzealous use of broad-spectrum antibiotics is the most likely cause for this increase. A study of patients undergoing cardiovascular surgery identified female sex, length of stay in the ICU, and duration of central venous catheterization as risk factors for postoperative *Candida* infections. Although presurgical *Candida* colonization is associated with a higher risk of fungal SSIs, routine preoperative use of prophylactic antifungal agents is not being advocated at this time.[26]

Antimicrobial stewardship programs are typically run by multidisciplinary teams in hospitals to promote responsible antimicrobial use and optimize antimicrobial therapy through multimodal educational and clinical interventions with an aim to reduce antimicrobial resistance and infection-related morbidity and mortality. Systematic reviews suggest that these programs are effective in reducing the development of antimicrobial resistance and hospital-acquired infections.[27] Typically antimicrobial stewardship programs target areas of the hospital where there is high use of antimicrobials but surgical units and operating rooms are often overlooked. Given that approximately 15% of all antimicrobials prescribed in hospital are for surgical prophylaxis and the opportunity to improve the outcomes of surgical patients with respect to SSIs, surgical units would benefit from antimicrobial stewardship programs and surgeons should be part of the multidisciplinary team.[28] Table 146-7

SCHEDULING ANTIBIOTIC ADMINISTRATION

③ ④ The following principles must be considered when providing antimicrobial surgical prophylaxis: (a) the agents should be delivered to the surgical site prior to the initial incision, and (b) bactericidal antibiotic concentrations should be maintained at the surgical site throughout the surgical procedure. Although animal and human models have demonstrated the efficacy of a single dose of an antibiotic administered just prior to bacterial contamination, long operations often require intraoperative doses of antibiotics to maintain adequate concentrations at the surgical site for the duration of surgery.[29] Antibiotic administration should be completed within 60 minutes prior to the initial incision, preferably at the time of anesthetic induction. Since the administration duration varies between antimicrobials, this needs to be considered when determining when to start the infusion. Administration of antibiotics too early may result in concentrations below the minimum inhibitory concentration (MIC) toward the end of the operation, and administration too late leaves the patient unprotected at the time of initial incision. In a study examining the timing of antibiotic administration to 2,847 patients receiving prophylaxis, Classen et al.[29] evaluated patients who received prophylaxis early (2-24 hours before surgery), preoperative prophylaxis (0-2 hours prior to surgery), perioperative prophylaxis (up to 3 hours after first incision), and postoperative prophylaxis (greater than 3 hours after the first incision). The risk of infection was lowest (0.6%) for patients who received preoperative prophylaxis, moderate (1.4%) for those who received perioperative antibiotics, and greatest for those who received postoperative antibiotics (3.3%) or preoperative antibiotics too early (3.8%). The risk for an SSI increases dramatically with each hour from the time of initial incision to the time when antibiotics are eventually administered. For these reasons, prophylactic antibiotics should not be prescribed to be given “on call to the operating room (OR),” which can occur two or more hours prior to the initial incision, nor should concurrent therapeutic antibiotics be relied on to provide adequate protection. In both situations, the chance for improperly timed doses is high. Although the landmark study by Classen et al.[29] confirmed that antimicrobial prophylaxis should be administered within 2 hours prior to the initial incision, administration immediately prior to the incision may not allow enough time for the drug to distribute throughout the tissues involved in the surgery.

In a large randomized controlled trial in Switzerland, hospitalized surgical patients were randomized to early (in the anesthesia room) or late (in the operating room) prophylactic antimicrobials.[30] A total of 2,589 patients in the early group received their antimicrobials a median of 42 minutes prior to the incision while 2,586 patients in the late group received their antimicrobials a median of 16 minutes prior to the incision. All patients received cefuroxime (plus metronidazole for colorectal surgery) as a single dose except for long operations where the cefuroxime (and metronidazole for colorectal surgery) was readministered every 4 hours during the operation. SSIs were 5% in both groups suggesting that the current recommendation to administer surgical prophylaxis within 60 minutes prior to the incision is adequate.

Despite the importance of appropriately timed prophylactic antibiotic therapy, many patients receive antibiotics outside of the optimal time window in relation to surgery. Potential barriers include antibiotics ordered after the patient has arrived in the OR, delayed antibiotic preparation or delivery, and use of antibiotics that require long infusion times. One retrospective study assessed the timing of prophylactic antibiotics in more than 32,000 patients and found that 91.9% of patients received an antibiotic dose within 60 minutes of the initial surgical incision.[31]

Although most studies comparing single versus multiple doses of prophylactic antibiotics have failed to show a benefit of multidose regimens, the duration of operations in these studies may not be as long as that frequently observed in clinical practice. Proponents of administering a second antibiotic dose during lengthy operations suggest that the risk for SSI is just as great at the end of surgery (during wound closing) as it is during the initial incision. One study of patients undergoing clean–contaminated operations suggests that procedures longer than 3 hours require a second intraoperative dose of cefazolin or substitution of cefazolin with a longer-acting antimicrobial agent.[5] A second study of patients undergoing elective colorectal surgery suggests that low serum antimicrobial concentrations at the time of surgical closure is the strongest predictor of postoperative SSI.[32] Studies of patients undergoing cardiac surgery also have demonstrated a higher infection rate among patients with undetectable antibiotic serum concentrations at the conclusion of the procedure.[33] Ideally antibiotic prophylaxis should be repeated when surgeries last longer than two half-lives of chosen antibiotic (ie, 4 hours for cefazolin) or if intraoperative blood loss exceeds 1.5 L.[7]

One strategy to ensure appropriate redosing of prophylactic antibiotics during long operations is use of a visual or auditory reminder system. One hospital reported its experience with such a system, finding that an automated reminder improved compliance and reduced SSIs. However, even with the reminder system, intraoperative redosing was done in only 68% of eligible patients.[34] Although optimizing the efficacy of antimicrobial prophylaxis is often the main focus of guideline documents, equal emphasis should be placed on avoidance of harms associated with unnecessary or prolonged courses of prophylactic antibiotics. A recent cohort study of more than 79,000 patients suggests that prolonged courses of prophylactic antibiotics (eg, more than 24-hour post–skin closure) was associated with higher risks of acute kidney injury and *C. difficile* infection without further reducing the rates of SSIs.[35]

ANTIMICROBIAL CHOICE

5 The choice of prophylactic antibiotic depends on the type of surgical procedure, the most frequent pathogens seen with this procedure, safety and efficacy profiles of the antimicrobial agent, current literature evidence supporting its use, and cost. Although most SSIs involve the patient's normal flora, antimicrobial selection also must take into account the susceptibility patterns of nosocomial pathogens within each institution. Typically, gram-positive coverage should be included in the choice of surgical prophylaxis because organisms such as *S. aureus* and *S. epidermidis* are encountered commonly as skin flora. The decision to broaden antibiotic prophylaxis to agents with gram-negative and anaerobic spectra of activity depends on both the surgical site (eg, upper respiratory, GI, or genitourinary tract) and whether the operation will transect a hollow viscous or mucous membrane that may contain resident flora.[4]

Although antimicrobial prophylaxis can be administered through a variety of routes (eg, oral, topical, or intramuscular), the parenteral route is favored because of the reliability by which adequate tissue concentrations may be acheived.[36] Cephalosporins are the most commonly prescribed agents for surgical prophylaxis because of their broad antimicrobial spectrum, favorable pharmacokinetic profile, low incidence of adverse side effects, and low cost. First-generation cephalosporins, such as cefazolin, are the preferred choice for surgical prophylaxis, particularly for clean surgical procedures.[4,5,10] In cases where broader gram-negative and anaerobic coverage is desired, antianaerobic cephalosporins, such as cefoxitin and cefotetan, are appropriate choices. Although third-generation cephalosporins (eg, ceftriaxone) have been advocated for prophylaxis because of their increased gram-negative coverage and prolonged half-lives, their inferior gram-positive and anaerobic activity and high cost have discouraged the widespread use of these agents.[4,5,10]

Allergic reactions are the most common side effects associated with cephalosporin use. Reactions can range from minor skin manifestations at the site of infusion to rash, pruritus, and rarely anaphylaxis (less than 0.02%). The structural similarity between penicillins and cephalosporins (each contains a β-lactam ring) has led to considerable confusion about the cross-allergenicity between these two classes of drugs. Twenty percent of the general population is labeled "penicillin allergic," yet of these patients, only 10% to 20% have positive results of a penicillin skin test.[37] The rate of cross-reactivity with cephalosporins is approximately 2%, but as only 20% of all "penicillin-allergic" patients truly are penicillin allergic, the true incidence of cross-reactivity likely is less than 1%. Routine penicillin skin testing is not cost-effective.[37] The administration of cephalosporins is both safe and cost-effective for many patients who are labeled "penicillin allergic," and they can be used by patients who have not experienced an immediate or type I penicillin allergy.

Vancomycin can be considered for prophylactic therapy in surgical procedures involving implantation of a prosthetic device in which the rate of MRSA is high.[38] If the risk of MRSA is low, and a β-lactam hypersensitivity exists, clindamycin can be used for many procedures instead of cefazolin to limit vancomycin use. Infusion-related side effects, such as thrombophlebitis and hypotension, particularly with vancomycin, usually can be controlled by adequate dilution and slower administration rates.

Pseudomembranous colitis secondary to cephalosporins is uncommon and generally easily treated with a short course of oral metronidazole. Although infrequent, bleeding abnormalities related to cephalosporin use have been reported.[39] The primary hematologic effect appears to be inhibition of vitamin K–dependent clotting factors that results in prolongation of the prothrombin time. The mechanism for this effect, most commonly seen with cefotetan, is related to the methylthiotetrazole side chain of the β-lactam molecule. Patients at greatest risk for this hypoprothrombinemic effect have received a prolonged course of these agents and have underlying risk factors for vitamin K deficiency, such as malnutrition.

Because inappropriate prophylactic antibiotic use not only can induce antibiotic resistance but also can negatively affect an institution's antibiotic budget, initiatives to curtail inappropriate antibiotic use have become the focus of many drug use evaluation efforts. Potential sources of inappropriate antibiotic prophylaxis include the use of broad-spectrum antimicrobials when a narrow-spectrum agent is warranted, extending prophylaxis for durations beyond that recommended in published guidelines, and using expensive antibiotics when equivalent, less expensive agents are available. Individualized institutional guidelines that take into account the best literature evidence, institution-based antibiotic susceptibility data, and surgeon preference are important tools for rationalizing antibiotic prophylaxis use.[40] This also highlights a potential role for antimicrobial stewardship.

RECOMMENDATIONS FOR SPECIFIC TYPES OF SURGERY

Guidelines for surgical prophylaxis usually are structured according to the tissues affected during an operation. Although many different surgical procedures may be performed at any one anatomic site, this method of categorization still is optimal because the factors related to the success of a prophylactic regimen, such as the endogenous flora that are expected and the pharmacokinetics, pharmacodynamics, and spectrum of selected antimicrobials, generally, are constant for a particular surgical site (see the discussion above). The choice of antimicrobial prophylaxis is always best evaluated using the results of properly conducted clinical trials. In the absence of studies specific to the procedure in question, extrapolation from data on regimens for different procedures in the same anatomic site in question usually can be made. Subsequent modifications to each prophylactic regimen should be based on intraoperative findings or events.

⑥A comprehensive review of the surgical prophylaxis literature is beyond the scope of this chapter, but important factors are reviewed here for common types/sites of surgery. Specific recommendations are summarized in Table 146-6. The reader is referred to published guidelines and review articles.[3–5,10,36,41]

TABLE 146-6

Most Likely Pathogens and Specific Recommendations for Surgical Prophylaxis

Type of Operation	Likely Pathogens	Recommended Prophylaxis Regimen[a]	Comments	Grade of Recommendation[b]
GI Surgery				
Gastroduodenal	Enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Cefazolin 1 g × 1	High-risk patients only (obstruction, hemorrhage, malignancy, acid suppression therapy, morbid obesity)	IA
Bariatric surgery	Enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Cefazolin 2 g x 1	Intraoperative redosing required for procedures longer than 4 hours	IB
Cholecystectomy	Enteric gram-negative bacilli, anaerobes	Cefazolin 1 g × 1 for high-risk patients; Laparoscopic: controversial	High-risk patients only (open biliary tract procedures, acute cholecystitis, common duct stones, previous biliary surgery, jaundice, age >60 years, obesity, diabetes mellitus)	IA
Transjugular intrahepatic portosystemic shunt (TIPS)	Enteric gram-negative bacilli, anaerobes	Ceftriaxone 1 g × 1	Longer-acting cephalosporins preferred	IA
Appendectomy	Enteric gram-negative bacilli, anaerobes	Cefoxitin or cefotetan 1 g × 1 or cefazolin 1 g plus metronidazole 1 g × 1	Second intraoperative dose of cefoxitin may be required if procedure lasts longer than 3 hours	IA

Colorectal	Enteric gram-negative bacilli, anaerobes	Orally: neomycin 1 g + erythromycin base 1 g at 1, 2, and 11 PM 1 day preoperatively plus mechanical bowel preparation IV: cefoxitin or cefotetan 1 g × 1	Role of mechanical bowel preparation is controversial. It is widely used despite evidence suggesting it may have no effect on SSI or other clinical outcomes	IA
GI endoscopy	Variable, depending on procedure, but typically enteric gram-negative bacilli, gram-positive cocci, oral anaerobes	Orally: amoxicillin 2 g × 1 IV: ampicillin 2 g × 1 or cefazolin 1 g × 1	Recommended only for high-risk patients undergoing high-risk procedures (see the text)	IA
Urologic Surgery				
Prostate resection, shock-wave lithotripsy, ureteroscopy	*E. coli*	Ciprofloxacin 500 mg orally or Trimethoprim–sulfamethoxazole 1 DS tablet	All patients with positive preoperative urine cultures should receive a course of antibiotic treatment	IA–IB
Removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy	*E. coli*	Ciprofloxacin 500 mg orally or Trimethoprim–sulfamethoxazole 1 DS tablet	Should be considered only in patients with risk factors (see the text)	IB
Gynecological Surgery				
Cesarean section	Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci	Cefazolin 1 g × 1 (< 80 kg), Cefazolin 2 g x 1 (≥ 80 kg). Add azithromycin 500 mg IV x 1 if non-elective procedure	Antimicrobial administration should be prior to the initial incision as opposed to after umbilical cord clamping	IA
Hysterectomy	Enteric gram-negative bacilli, anaerobes, group B streptococci, enterococci	Vaginal: cefazolin 2 g × 1 (3 g if > 120 kg) Abdominal: cefotetan 1 g × 1 or cefazolin 2 g × 1	Metronidazole 1 g IV × 1 is recommended alternative for penicillin allergy	IA
Head-and-Neck Surgery				
Maxillofacial surgery	*Staphylococcus aureus*, streptococci spp., oral anaerobes	Cefazolin 2 g or clindamycin 600 mg	Repeat intraoperative dose for operations longer than 4 hours	IA
Head-and-neck cancer resection	*S. aureus*, streptococci spp., oral anaerobes	Clindamycin 600 mg at induction and every 8 hours × 2 more doses	Ampicillin / sulbactam 3 g for clean–contaminated procedures	IA
Cardiothoracic Surgery				
Cardiac surgery	*S. aureus*, *S. epidermidis*,	Cefazolin 1 g every 8 hours × 48	Patients >80 kg (176 lb) should	IA

	Corynebacterium	hours Intranasal mupirocin twice daily for 5 days preoperatively for patients colonized with *S. aureus*	receive 2 g of cefazolin instead; in areas with high prevalence of *S. aureus* resistance, vancomycin should be considered	
Thoracic surgery	*S. aureus*, *S. epidermidis*, *Corynebacterium*, enteric gram-negative bacilli	Cefuroxime 750 mg IV every 8 hours × 48 hours	First-generation cephalosporins are deemed inadequate, and shorter durations of prophylaxis have not been adequately studied	IA
Vascular Surgery				
Abdominal aorta and lower extremity vascular surgery	*S. aureus*, *S. epidermidis*, enteric gram-negative bacilli	Cefazolin 1 g at induction and every 8 hours × 2 more doses	Although complications from infections may be infrequent, graft infections are associated with significant morbidity	IB
Orthopedic Surgery				
Joint replacement	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours × 2 more doses Intranasal mupirocin twice daily for 5 days preoperatively for patients colonized with *S. aureus*	Vancomycin reserved for penicillin-allergic patients or where institutional prevalence of methicillin-resistant *S. aureus* warrants use	IA
Hip fracture repair	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 preoperatively, then every 8 hours for 48 hours	Compound fractures are treated as if infection is presumed	IA
Open/compound fractures	*S. aureus*, *S. epidermidis*, gram-negativebacilli, polymicrobial	Cefazolin 1 g × 1 preoperatively, then every 8 hours for a course of presumed infection	Gram-negative coverage (ie, gentamicin) often indicated for severe open fractures	IA
Neurosurgery				
CSF shunt procedures	*S. aureus*, *S. epidermidis*	Cefazolin 1 g every 8 hours × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials	IA
Spinal surgery	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1	Limited number of clinical trials comparing different treatment regimens	IB
CSF shunt procedures	*S. aureus*, *S. epidermidis*	Cefazolin 1 g every 8 hours × 3 doses or ceftriaxone 2 g × 1	No agents have been shown to be better than cefazolin in randomized comparative trials	IA
Craniotomy	*S. aureus*, *S. epidermidis*	Cefazolin 1 g × 1 or cefotaxime 1 g × 1	Vancomycin 1 g IV × 1 can be substituted for patients with penicillin allergy	IA

CSF, cerebrospinal fluid; DS, double strength.

[a] One-time doses are optimally infused at induction of anesthesia except as noted. Repeat doses may be required for long procedures. See the text for references.

[b] Strength of recommendations: Category IA: Strongly recommended and supported by well-designed experimental, clinical, or epidemiologic studies. Category IB: Strongly recommended and supported by some experimental, clinical, or epidemiologic studies and strong theoretical rationale. Category II: Suggested and supported by suggestive clinical or epidemiologic studies or theoretical rationale.

Gastrointestinal Surgery

GI surgery can be categorized according to surgical site and infectious risk. Gastroduodenal surgery and hepatobiliary surgery generally are considered to be clean or clean–contaminated surgeries, with SSI rates generally less than 5%. Colorectal surgery, including appendectomies, is considered contaminated because of the large quantities and polymicrobial nature of bacterial flora within the colon. SSI rates for these types of surgeries generally range from 15% to 30%. Emergent abdominal surgery involving bowel perforation or peritonitis is considered a dirty surgical procedure, associated with a greater than 30% risk of SSI, and should be treated with therapeutic rather than prophylactic antibiotics.[4]

Gastroduodenal Surgery

Insignificant numbers of bacteria usually are found in the stomach and duodenum because of their acidity. The rate of SSIs in gastroduodenal surgery generally is low, so procedures in this region can be classified as clean. The risk for an SSI in this population increases with any condition that can lead to bacterial overgrowth, such as obstruction, hemorrhage, or malignancy, or increasing the pH of gastroduodenal secretions with concomitant acid suppression therapy. Antimicrobial prophylaxis is of clinical benefit only in this high-risk population. In most cases, a single IV dose of cefazolin will provide adequate prophylaxis.[10] Antimicrobial prophylaxis is indicated in esophageal surgery only in the presence of obstruction. Postoperative therapeutic antibiotics may be indicated if perforation is detected during surgery, depending on whether an established infection is present.

Use of antibiotic prophylaxis for percutaneous endoscopic gastrostomy placement is also warranted. Postoperative peristomal infection can occur in up to 30% of patients and a systematic review of 12 trials involving 1,271 patients found a significant reduction in peristomal infections with antimicrobial prophylaxis (OR 0.36, 95% CI 0.26-0.50).[42] A single dose of cefazolin given 30 minutes preoperatively is preferred over longer regimens.

There are few well-designed clinical trials of antimicrobial prophylaxis in bariatric surgery (ie, Roux en Y gastric bypass, gastric banding, sleeve gastrectomy). However, given that obesity is a consistently identified risk factor for SSIs, guidelines do promote antimicrobial prophylaxis with cefazolin as this is the agent that has been most studied.[43] Dosing is still controversial, but at higher doses is generally recommended based on greater volumes of distribution in morbidly obese patients.[10] Pharmacokinetic studies suggest that 2 g of cefazolin provided adequate tissue levels for 4.8 hours.[43]

Hepatobiliary Surgery

Although bile normally is sterile, and the SSI rate after biliary surgery is low, antibiotic prophylaxis is of benefit in this population. Bile contamination (bactobilia) can increase the frequency of SSIs and is present in many patients (eg, those with acute cholecystitis or biliary obstruction and those of advanced age).[41] In general, however, the correlation between bactobilia in surgical specimens and the subsequent pathogens implicated in an SSI is poor. The most frequently encountered organisms are *E. coli*, *Klebsiella* species, and enterococci. *Pseudomonas* is an uncommon finding in the absence of cholangitis. Most of the SSI literature on biliary tract surgery pertains to cholecystectomy while more recent trials pertain to laparoscopic procedures which have eclipsed the traditional open cholecystectomy because of a reduction in recovery time and hospital stay. The evidence in open cholecystectomy strongly supports the use of antimicrobial prophylaxis while the evidence for laparoscopic procedures is less impressive.[10] Trials comparing first-, second-, and third-generation cephalosporins have not demonstrated benefit over single-dose cefazolin prophylaxis even in high-risk patients (eg, age greater than 60 years, previous biliary surgery, acute cholecystitis, jaundice, obesity, diabetes, and common bile duct stones).[44] Ciprofloxacin and levofloxacin are effective alternatives for β-lactam-allergic patients undergoing open cholecystectomy.[45,46] In fact, oral levofloxacin appears to provide similar intraoperative gallbladder tissue concentrations.[46] For patients undergoing elective laparoscopic cholecystectomy, antibiotic prophylaxis has traditionally not been recommended but newer trials and systematic reviews are conflicting and assessments of current practice are reflective of this.[47,48] Detection of an active infection during surgery (eg, gangrenous gallbladder and suppurative cholangitis) is an indication for a course of postoperative therapeutic antibiotics. The risk for SSIs in cirrhotic patients undergoing transjugular intrahepatic portosystemic shunt surgery may be reduced with a single prophylactic dose of ceftriaxone,[49] but not with single doses of shorter-acting cephalosporins.[50]

Appendectomy

Acute appendicitis can be broadly categorized as complicated (evidence of perforation, gangrene, peritonitis, or abscess formation) or uncomplicated. Complicated appendicitis should be treated as an active intra-abdominal infection. While appendectomy for uncomplicated appendicitis is more common it has been associated with SSI rates of 9% to 30% in the absence of antimicrobial prophylaxis. Randomized controlled trials do suggest that preoperative antimicrobials are effective at reducing this risk and should be administered in all cases.[51] Numerous antibiotic regimens, all with activity against gram-positive and gram-negative aerobes and anaerobic pathogens, are effective in reducing SSI incidence.[41] A cephalosporin with antianaerobic activity, such as cefoxitin or cefotetan, is recommended as first-line therapy; however, a comparative trial of cefoxitin and cefotetan suggests that cefotetan may be superior, possibly because of its longer duration of action.[52] Alternatively, cefazolin in combination with metronidazole is also effective. In patients with β-lactam allergy, metronidazole in combination with gentamicin is an effective regimen. Broad-spectrum antibiotics covering nosocomial pathogens (eg, *Pseudomonas*) do not further reduce SSI risk and instead may increase the cost of therapy and promote bacterial resistance. Although single-dose therapy with cefotetan is adequate, prophylaxis with cefoxitin may require intraoperative redosing if the procedure extends beyond 3 hours.

Colorectal Surgery

In the absence of adequate prophylactic therapy, the risk for SSI after colorectal surgery is high (5.4%-23.2%) because of the significant bacterial counts in fecal material present in the colon (frequently greater than 10^9 per gram).[53] Anaerobes and gram-negative aerobes predominate, but gram-positive aerobes also may play an important role. Reducing this bacterial load with a thorough bowel preparation regimen (4 L of polyethylene glycol solution or 90 mL of sodium phosphate solution administered orally the day before surgery) is controversial; however, 99% of United States surgeons in a survey routinely use mechanical preparation.[54] The presumed value of a mechanical bowel preparation goes beyond its effect on SSIs as it is also thought to facilitate bowel manipulation, enable safe passage of surgical instruments, and allow for intraoperative colonoscopy if needed. A randomized trial of 380 patients undergoing elective colorectal surgery suggests that SSIs are not reduced by preoperative mechanical bowel preparation.[55] This finding was confirmed in two meta-analyses showing that mechanical bowel preparation does not reduce the risk of anastomotic leakage or other complications, including postoperative infection.[56,57] Despite this new evidence, mechanical bowel preparations continue to be a standard of practice prior to elective bowel surgery.

Risk factors for SSIs include age over 60 years, hypoalbuminemia, poor preoperative bowel preparation, corticosteroid therapy, malignancy, and operations lasting longer than 3.5 hours.[10] Antimicrobial prophylaxis reduced mortality from 11.2% to 4.5% in a pooled analysis of trials comparing antimicrobial prophylaxis with no prophylaxis for colon surgery.[58] Effective antibiotic prophylaxis consisting of an oral and IV regimen reduces even further the risk for an SSI. A Cochrane review comparing oral, IV, and combination regimens found that while each one was more effective at reducing SSI than placebo, combination therapy (oral and IV) was superior to oral regimens alone (OR 0.52 [0.35, 0.76]) and IV regimens alone (OR 0.55 [0.43, 0.71]).[59] This finding was confirmed by a systematic review of 14 trials, and now clinical practice guidelines from the American Society of Colon and Rectal Surgeons recommends the combination of oral antibiotics and mechanical bowel preparation preoperatively in addition to intravenous antibiotics at the time of surgery.[53,60]

Several oral regimens designed to reduce bacterial counts in the colon have been studied.[41] The combination of 1-g neomycin and 1-g erythromycin base given orally 19, 18, and 9 hours preoperatively is the regimen most commonly used in the United States.[60] Neomycin is poorly absorbed but provides intraluminal concentrations that are high enough to effectively kill most gram-negative aerobes. Oral erythromycin is only partially absorbed but still produces concentrations in the colon that are sufficient to suppress common anaerobes. If surgery is postponed, the antibiotics must be readministered to maintain efficacy. Optimally, the bowel preparation regimen (if used) should be completed prior to starting the oral antibiotic regimen. This is of particular concern because most procedures now are performed electively on a "same-day surgery" basis. In this case, the bowel preparation regimen is self-administered by the patient at home on the day prior to hospital admission, and compliance cannot be monitored carefully.

Single-dose cephalosporins are the most used and studied preoperative IV antimicrobial. Cefoxitin or cefotetan is used most commonly, but other second- and some third-generation cephalosporins also are effective.[61] The role of metronidazole in combination with cephalosporin therapy is unclear. Only retrospective evidence suggests that the addition of metronidazole to a cephalosporin or extended-spectrum penicillin provides additional benefit.[62] Until this finding is confirmed in prospective studies, metronidazole should be reserved for combination therapy with cephalosporins with poor anaerobic coverage (eg, cefazolin). At this time, the evidence recommending the addition of metronidazole to cephalosporins with anaerobic activity (eg, cefotaxime, cefoxitin, and ceftriaxone) is insufficient.[63] For β-lactam-allergic patients, perioperative doses of gentamicin and metronidazole have been used. Postoperative antibiotics generally are unnecessary in the absence of any untoward events or findings during surgery. IV antibiotics are required for colostomy reversal and rectal resection because enterally administered antibiotics will not reach the distal segment that is to be reanastomosed or resected.[64]

Gastrointestinal Endoscopy

Despite the large number of endoscopic procedures performed each year, the rate of postprocedural infection is relatively low. The highest bacteremia rates have been reported in patients undergoing esophageal dilation for stricture or sclerotherapy for management of esophageal varices. Although postprocedural bacteremia can occur in as many as 22% of patients, the bacteremia usually is transient (less than 30 minutes) and rarely results in clinically significant infection. Therefore, antimicrobial prophylaxis is routinely recommended only for high-risk patients (eg, patients with prosthetic heart valves, a history of endocarditis, systemic-pulmonary shunt, synthetic vascular graft less than 1-year-old, complex cyanotic congenital heart disease, obstructed bile duct, or liver cirrhosis, as well as immunocompromised patients) undergoing high-risk procedures (eg, stricture dilation, variceal sclerotherapy, and endoscopic retrograde cholangiopancreatography, ERCP).[65] Single-dose preprocedural regimens similar to those for endocarditis prophylaxis are most common (amoxicillin for patients who can tolerate oral premedication or either IV ampicillin or cefazolin). A meta-analysis of antimicrobial prophylaxis for endoscopic placement of percutaneous feeding tubes also suggests that a single preoperative dose of antibiotics reduces the risk of postoperative infection compared with no antibiotic (6.4% vs 24%).[66] Consensus guidelines have adopted this recommendation and suggest a single dose of cefazolin within 30 minutes prior to the procedure.[65]

Urologic Surgery

Preoperative bacteriuria is the most important risk factor for development of an SSI after urologic surgery. All patients should have a preoperative urinalysis and should receive therapeutic antibiotics if bacteriuria is detected. Patients undergoing clean urologic procedures with sterile urine preoperatively are at low risk for developing an SSI, and antimicrobial prophylaxis is not recommended.[10] Antibiotic prophylaxis is recommended for all patients undergoing transurethral resection of the prostate or bladders tumors, shock-wave lithotripsy, percutaneous renal surgery, or ureteroscopy.[67] The exact incidence of SSIs in this population is obscured by the frequent use of postoperative urinary catheters and the subsequent risk of bacteriuria. *E. coli* is the most frequently encountered organism. Routine use of broad-spectrum antibiotics, such as third-generation cephalosporins and fluoroquinolones, does not decrease SSI rates more than cefazolin, but the ability to administer fluoroquinolones orally rather than IV makes antimicrobial prophylaxis with ciprofloxacin easier and less expensive.[68] First- or second-generation cephalosporins are considered the antimicrobial agents of choice for patients undergoing open or laparoscopic procedures involving entry into the urinary tract and any urologic surgical procedures involving the intestine, rectum, vagina, or implanted prosthesis.[67] The evidence supporting antimicrobial prophylaxis for the removal of external urinary catheters, cystography, urodynamic studies, simple cystourethroscopy, and open or laparoscopic urologic procedures that do not involve entry into the urinary tract is not as evident. Only patients considered to have risk factors (patients of advanced age; those with anatomic anomalies, poor nutritional history, externalized catheters, colonized endogenous/exogenous material, or distant coexistent infection; smokers; immunocompromised patients; and those who are hospitalized for a prolonged stay) should receive antimicrobial prophylaxis.[67]

Obstetric and Gynecologic Surgeries

Cesarean Section

Cesarean section is the most frequently performed surgical procedure in the United States.[10] Prophylactic antibiotics are given to prevent endometritis, the most commonly occurring SSI. In the past, antibiotics were recommended for only high-risk patients, including those with premature membrane rupture or those not receiving prenatal care. Several large trials, as well as a meta-analysis of 95 trials, have shown benefit in administering prophylactic antibiotics to all women undergoing emergent or elective cesarean section regardless of their underlying risk factors.[69] Cefazolin remains the drug of choice despite the wide spectrum of potential pathogens, and a single 2-g dose for patients weighing 80 kg or more and a single 1-g dose for patients weighing less than 80 kg is recommended.[70] For patients with a β-lactam allergy, preoperative metronidazole is an acceptable alternative.[69] In women undergoing nonelective cesarean section, a composite outcome of endometritis, wound infection, or other infection occurring within 6 weeks was 6.1% in women who received extended spectrum coverage with azithromycin plus cefazolin versus 12% in those who received cefazolin alone.[71] This study makes a strong argument for extending the spectrum of coverage with azithromycin in addition to the standard cephalosporin regimen for patients undergoing nonelective cesarean section.

During a cesarean section, unlike other surgical procedures, the most appropriate timing of antibiotic administration has been a source of controversy. Traditionally, antimicrobials were administered after the initial incision and when the umbilical cord was clamped in an attempt to minimize infant drug exposure, which theoretically could mask the signs of infection and induce antimicrobial resistance. The most recent CDC guidelines suggest that high-quality evidence supports antimicrobial administration at the time of the initial incision instead of at the time of umbilical cord clamping.[4] A meta-analysis of seven randomized controlled trials reports a 43% reduction in postpartum endometritis without an increase in neonatal sepsis or antimicrobial resistance.[4]

Hysterectomy

The most important factor affecting the incidence of SSI after hysterectomy is the type of procedure performed. Vaginal hysterectomies are associated with a high rate of postoperative infection when performed without the benefit of prophylactic antibiotics because of the polymicrobial flora normally present at the operative site.[72] As with cesarean sections, cefazolin is the drug of choice for vaginal hysterectomies despite the wide spectrum of possible pathogens.[72] The American College of Obstetricians and Gynecologists (ACOG) recommends a single dose of either cefazolin or cefoxitin.[73] For patients with a β-lactam allergy, a single preoperative dose of either metronidazole or doxycycline also is effective.[73]

Prophylactic antibiotics are recommended for abdominal hysterectomy despite the lack of bacterial contamination from the vaginal flora. Single-dose cefotetan was superior to single-dose cefazolin,[74] and the investigators suggested that cefotetan should be the drug of choice for abdominal hysterectomies. However, other investigators suggested that either agent is appropriate, provided 24 hours of antimicrobial coverage is not exceeded.[10] The ACOG guidelines suggest that first- (such as cefazolin), second- (such as cefotetan), or third-generation cephalosporins can be used for prophylaxis.[73] Metronidazole plus an aminoglycoside or fluoroquinolone is also effective and can be used if patients are allergic to β-lactam antibiotics. Antibiotic prophylaxis may not be required in laparoscopic gynecologic surgery or tubal microsurgery.[75] As with other surgical procedures, perioperative events and findings may require the use of therapeutic antibiotics after surgery.

Head-and-Neck Surgery

The use of prophylactic antibiotics during head-and-neck surgery depends on the procedure type. Clean procedures (per NRC definition), such as thyroidectomy, lymph node excision, and simple tooth extraction, are associated with a low incidence of SSI. Antimicrobial prophylaxis is not recommended for these procedures. Head-and-neck surgeries involving an incision through a mucosal layer are associated with a higher risk for SSI but antimicrobial prophylaxis is not always associated with a reduction in SSI (ie, adenoidectomy, tonsillectomy, and septoplasty).[10] The normal flora of the mouth is polymicrobial; both anaerobes and gram-positive aerobes predominate. Although typical doses of cefazolin usually are ineffective for anaerobic infections, a 2-g dose produces concentrations high enough to inhibit these organisms. A single dose of clindamycin is adequate for prophylaxis in maxillofacial surgery unless the procedure lasts longer than 4 hours, when a second dose should be administered intraoperatively.[76] The greatest evidence for antimicrobial prophylaxis is in head-and-neck cancer resection surgeries. For most head-and-neck cancer resection surgeries, including free-flap reconstruction, 24 hours of clindamycin is appropriate, and no additional benefit of extending therapy beyond 24 hours is seen. Ampicillin/sulbactam is preferred to clindamycin to cover aerobic, anaerobic, and gram-negative bacteria in clean–contaminated oncologic surgery.[77] Topical therapy with clindamycin, amoxicillin–clavulanate, and ticarcillin–clavulanate has been described in small trials, but the exact role of topical antibiotics is not defined.[78] Antimicrobial prophylaxis is not indicated for endoscopic sinus surgery without nasal packing.[36]

Cardiothoracic Surgery

Although cardiac surgery generally is considered a clean procedure, antibiotic prophylaxis lowers SSI incidence.[41] The substantial morbidity related to an SSI in this population, coupled with the routine implementation of prosthetic devices, further justifies the routine use of prophylaxis.[79] Patients who develop SSIs after coronary artery bypass graft surgery have a mortality rate of 22% at 1 year compared with 0.6% for those who do not develop an SSI.[80] Risk factors for developing an SSI after cardiac surgery include obesity, renal insufficiency, connective tissue disease, reexploration for bleeding, and poorly timed administration of antibiotics.[79] Skin flora pathogens predominate; gram-negative organisms are rare.

Cefazolin has been studied extensively and is considered the drug of choice. Although several studies and a meta-analysis advocate the use of second-generation cephalosporins (eg, cefuroxime) rather than cefazolin, various methodologic flaws in these studies have limited the extrapolation of these results to practice. Cefazolin was as effective as cefuroxime in a large, randomized trial of 702 patients undergoing open heart surgery and thus remains the standard of care.[81] Both patient weight and timing of cefazolin administration relative to surgery must be considered when developing a dosing strategy. Patients weighing greater than 80 kg (176 lb) should receive 2-g cefazolin rather than 1 g. Doses should be administered no earlier than 60 minutes before the first incision and no later than the beginning of induction.[77] Extending therapy beyond 48 hours does not further reduce SSI rates. Single-dose cefazolin therapy may be sufficient but is not recommended by the Society of Thoracic Surgeons at this time pending further study.[82]

⑦Routine vancomycin administration may be justified in hospitals having a high incidence of MRSA or when sternal wounds are to be explored surgically for possible mediastinitis. However, a large comparative trial enrolling almost 900 patients in a single center with a high prevalence of MRSA infections found that both cefazolin and vancomycin had similar efficacy in preventing SSI in patients undergoing cardiac surgery that required sternotomy.[83] Mediastinitis constitutes a failure of a prior prophylactic regimen. Continued postoperative vancomycin should be guided by culture and sensitivity data.[37] Subsequent antibiotic therapy is guided by intraoperative findings.

Since *S. aureus* is routinely identified as the most common pathogen in SSIs after cardiac surgery, several studies have investigated alternative methods for preoperative eradication including nasal mupirocin administration (ie, twice daily for 5 days preoperatively) and chlorhexidine body wash (ie, daily preoperatively for up to 5 days). A bundled approach (ie, more than one intervention implemented together) in addition to preoperative antimicrobials appears to further reduce the risk of postoperative SSI in both cardiac and orthopedic surgeries.[11,84]

Pulmonary resection is associated with significant SSI risk, and prophylactic antibiotics have an established role in preventing postoperative infectious morbidity. Pleuropulmonary infections are much more common than wound infections, and pathogenic organisms likely migrate from the oral cavity or pharynx.[85] First-generation cephalosporins are inadequate; 48 hours of cefuroxime is preferred. A regimen of ampicillin–sulbactam is superior to first-generation cephalosporins, but further studies are required before this agent can be recommended as first-line prophylactic therapy.[86]

Vascular Surgery

Vascular surgery, like cardiac surgery, generally is considered clean by NRC criteria. Although vascular graft infections occur infrequently (3%-5%), the associated morbidity and mortality are extensive because treatment often requires surgical graft removal along with therapeutic antibiotic therapy.[87] Prophylactic antibiotics are of benefit, particularly for procedures involving the abdominal aorta, lower extremities, or the implantation of prosthetic devices. Cefazolin is regarded as the drug of choice. Twenty-four hours of prophylaxis with cefazolin is adequate; longer courses may lead to bacterial resistance.[88] For patients with β-lactam allergy, 24 hours of oral ciprofloxacin was effective.[87]

Orthopedic Surgery

Most orthopedic surgery is clean by definition; thus, prophylactic antibiotics generally are indicated only when prosthetic materials (eg, pins, plates, and artificial joints) are implanted.[23] A late-occurring infectious complication in this surgical population can result in substantial morbidity and may lead to prosthesis failure and subsequent removal. Staphylococci species are the most frequently encountered pathogens; gram-negative aerobes are infrequent. The use of cefazolin is supported by substantial evidence in the literature and therefore is the prophylactic agent of choice. Vancomycin, although effective, is not recommended for routine use unless a patient has a documented history of a serious allergy to β-lactams, or the propensity for MRSA infections at a particular institution necessitates its use. The current recommended duration of prophylaxis for joint replacement and hip fracture surgery is 24 hours.[10] Antibiotic-impregnated cement and beads have been used to lower SSI rates, but conclusive data regarding their efficacy are lacking.[23]

Duration of prophylaxis for the surgical repair of long bone fractures depends on the nature of the fracture. Multiple doses of prophylactic antibiotics offer no advantage over a single preoperative dose for repair of closed bone fractures and is more cost effective.[89,90] Patients suffering open (compound) fractures are particularly susceptible to infection because bacterial contamination almost always has occurred already. Under these circumstances, the use of antibiotics is presumptive. In this setting, cefazolin often is combined with an aminoglycoside, but controlled trials are lacking.[91] A clinical trial comparing clindamycin and cloxacillin suggests that clindamycin is superior and may be appropriate as monotherapy for Gustilo type I and II open fractures but not for type III fractures, for which added gram-negative activity is recommended.[92] Duration of antibiotic therapy is highly variable and depends on surgical findings during debridement, results of intraoperative cultures, and clinical status. A prospective trial and subsequent systematic review comparing short (less than 24 hours) and long (greater than 24 hours) courses of antimicrobial prophylaxis for severe trauma suggests that longer courses of antibiotics do not offer additional benefit and may be associated with the development of resistant infections.[93] However, established joint infections and osteomyelitis require an extended course of therapeutic antibiotics.

As in cardiac surgery, there is evidence to support the use of preoperative intranasal mupirocin and chlorhexidine body wash for patients colonized with *S. aureus*. For elective procedures, patients would be instructed to administer these at home in the days prior to the surgery. This bundled approach appears to further reduce the risk of postoperative SSI in addition to preoperative antimicrobials.[11,84]

Neurosurgery

The rates of SSI after clean neurosurgical operations (ie, craniotomy, spinal procedures) are low; however, the morbidity and mortality of central nervous system SSI, should they occur, are high. Preoperative antibiotics are effective at reducing SSI rates and are recommended even in clean procedures.[94,95] While many antimicrobials have been studied, a single dose of cefazolin is what is recommended.[10]

Procedures involving cerebrospinal fluid (CSF) shunt placement should be considered separately because this procedure involves placement of a foreign body and is associated with higher infection rates. A study of 780 patients undergoing neurosurgical procedures that included shunt surgery reported that single doses of cefotaxime and trimethoprim–sulfamethoxazole were equally effective in preventing SSIs.[96] Most studies of procedures involving a shunt have been small in size and do not consistently show lower infection rates with antibiotic prophylaxis, although the results of a systematic review and meta-analysis suggest that a significant improvement in the incidence of shunt infection with 24 hours of systemic antibiotics (ie, cefazolin) and the use of antibiotic-impregnated catheters independently.[97]

SSIs associated with spinal surgery are rare but devastating when they occur. The use of antimicrobial prophylaxis in this setting is warranted and recommended.[93] Large randomized, controlled trials are lacking, but cefazolin is the antibiotic recommended most commonly. Cephalosporin penetration into the vertebral disk has been questioned. Some small studies suggest that the addition of gentamicin, which has better penetration, might be warranted; however, there is a paucity of clinical trials comparing these two regimens.[98]

NONPHARMACOLOGIC INTERVENTIONS

Strategies other than antimicrobial and aseptic technique for reducing postoperative infections have been investigated in different types of surgeries. The most commonly cited and practiced interventions include intraoperative maintenance of normothermia, provision of supplemental oxygen in the perioperative period, and aggressive perioperative glucose control. Although interventions to maintain normothermia intraoperatively provide supplemental oxygen in the perioperative period, and aggressively control perioperative glucose show a significant reduction in SSI, they cannot be generalized to all types of surgeries. However, given the simplicity and low cost of these interventions, many clinicians consider applying these measures outside of the studied population(s).

Core body temperature can fall by 1°C to 1.5°C intraoperatively in patients under general anesthesia. Intraoperative hypothermia has been associated with impaired immune function, decreased blood flow to the surgical site, decreased tissue oxygen tension, and an increased risk of SSI. Efforts to maintain intraoperative normothermia should be exercised and may include the use of warming blankets and IV fluid warmers to maintain core body temperature between 36°C and 38°C. One prospective trial of 200 patients undergoing colorectal surgery found that maintenance of normothermia reduced postoperative infection rates along with other morbidity parameters, including length of stay.[99] CDC guidelines promote maintaining normothermia with strong recommendation based on moderate- to high-quality evidence.[4]

Low oxygen tension in the tissues that make up the surgical site increases the risk of bacterial colonization and subsequent SSI by decreasing the efficiency of neutrophil activity. Administration of high concentrations of oxygen (80% via ventilator or 12 L/min via a nonrebreather mask) reduced postoperative infection rates significantly in a multicenter randomized trial of 500 patients undergoing colorectal surgery.[100] Supplemental oxygen during the intraoperative and immediate postoperative periods is recommended even in patients with normal pulmonary function.[4]

Diabetes and poor glucose control are well-known risk factors for SSI. The increased risk of infection is thought to be due to both macrovascular (vasculopathy and venoocclusive disease) and microvascular (subtle immunologic deficiencies, including neutrophil dysfunction and reduced complement and antibody activity) complications. Aggressive control of perioperative blood glucose not only decreases the incidence of SSI in diabetics and nondiabetics but is also a better predictor of SSI risk than long-term glucose control (eg, as measured by hemoglobin A1C).[7,101] Perioperative blood glucose levels should be checked in all patients regardless of diabetes status and glucose targets of 6.1-8.3 mmol/L (110-150 mg/dL) are recommended.[4] In cardiac surgery the recommended target is <10 mmol/L (180 mg/dL).[7]

Prophylactic antibiotics are only effective when therapeutic concentrations in the surgical field are maintained for the entire duration of the surgery. While consideration of drug half-life in the context of the duration of surgery has been discussed earlier in this chapter, other patient-related factors may influence the effectiveness of antibiotic prophylaxis and warrant consideration when choosing a prophylactic regimen (Table 146-7).

TABLE 146-7

Strategies for Implementing an Institutional Program to Ensure Appropriate Use of Antimicrobial Prophylaxis in Surgery

1. **Educate:** Develop an educational program that enforces the importance and rationale of timely antimicrobial prophylaxis. Make this educational program available to all healthcare practitioners involved in the patient's care.
2. **Standardize the ordering process**: Establish a protocol (eg, a preprinted order sheet) that standardizes antibiotic choice according to current published evidence, formulary availability, institutional resistance patterns, and cost.
3. **Standardize the delivery and administration process**: Use system that ensures antibiotics are prepared and delivered to the holding area in a timely fashion. Standardize the administration time to <1 hour preoperatively. Designate responsibility and accountability for antibiotic administration. Provide visible reminders to prescribe/administer prophylactic antibiotics (eg, checklists). Develop a system to remind surgeons/nurses to readminister antibiotics intraoperatively during long procedures.
4. **Provide feedback**: Follow up with regular reports of compliance and infection rates.

Obese patients require larger doses of prophylactic antibiotics to maintain therapeutic drug levels when compared to nonobese patients. Patients with a body mass index greater than 40 kg/m^2 are more likely to have subtherapeutic concentrations at the end of surgery with cefazolin 1 g preoperatively (and intraoperative for surgeries greater than 3 hours) and thus should receive 2 g doses.[102] Underlying disease states that may affect antibiotic metabolism and/or elimination should be considered when developing a prophylactic regimen. For example, patients with thermal burn and spinal cord injuries eliminate certain classes of antibiotics, primarily the aminoglycosides and β-lactams, at unusually high rates compared with controls and will need more frequent intraoperative dosing. Conversely, individuals with renal failure may need less frequent dosing of renally cleared antibiotics. For example, while intraoperative dosing for cefazolin should be every 3 to 4 hours in patients with normal renal function, this interval should be extended to 8 hours for patients with creatinine clearances of less than 50 mL/min (0.83 mL/s). Individuals who are aggressively fluid resuscitated pre- or intraoperatively or those undergoing cardiac bypass may have altered antibiotic disposition related to increased volume of distribution and reduced total body clearance and may need larger doses (ie, 2-g cefazolin).

EVALUATION OF THERAPEUTIC OUTCOMES

When evaluating the outcome of surgical antibiotic prophylaxis, it is important to differentiate any potential SSI from other postoperative infection or complication. Although fever and leukocytosis are common in the immediate postoperative period, they typically resolve with prompt ambulation, timely removal of invasive devices, prevention and/or resolution of atelectasis through optimal respiratory care, and effective analgesia. It is important to remember that the emergence of distal infections, such as pneumonia, does not constitute a failure of surgical prophylaxis. Prophylaxis should be as short as possible because prolonged prophylactic regimens may contribute to the selection of resistant organisms and may make any infection more difficult to treat.

Surgical site appearance is the most important determinant of the presence of an infection. Drainage of pus from the incision accompanied by redness, warmth, and pain or tenderness is highly suggestive of an SSI. By definition, any surgical site that requires incision and drainage by the surgeon is considered infected regardless of appearance. Failure to heal and wound dehiscence also are seen with SSIs, although the surgical technique and nutritional status may be important contributing factors.

The presentation of signs and symptoms consistent with an SSI in relation to previous surgery is an important consideration when evaluating therapeutic outcomes after surgical prophylaxis. Many SSIs will not be evident during acute hospitalization. In fact, SSIs may not become evident until up to 30 days later or, in the case of prosthesis implantation, up to 1 year later. Thus, the true incidence of SSI can be determined only by completing comprehensive postdischarge surveillance. All studies investigating the efficacy of surgical prophylaxis must include adequate postdischarge follow-up to be able to thoroughly assess the success of any prophylactic regimen.

SELF-ASSESSMENT QUESTIONS

1. A patient undergoing a cholecystectomy for acute cholecystitis requires:
    - A. No antibiotic therapy
    - B. Prophylactic antibiotic therapy
    - C. Presumptive antibiotic therapy
    - D. Therapeutic antibiotic therapy
2. According to the National Research Council classification of surgical site infection, antibiotic therapy is *not* required for:
    - A. Clean procedures

B. Clean–contaminated procedures

C. Contaminated procedures

D. A and B

3. Which of the following is not considered patient-specific risk factors for surgical site infections?

A. Smoking history

B. Preoperative nutritional status

C. Male gender

D. Diabetes

4. Which of the following statements about preoperative nutrition is *true*?

A. Preoperative dietary supplementation with glutamine reduces the risk of postoperative surgical site infections.

B. Preoperative dietary supplementation with arginine reduces the risk of postoperative surgical site infections.

C. Preoperative dietary supplementation with omega-3 fatty acids reduces the risk of postoperative surgical site infections.

D. No dietary supplements have been shown to decrease postoperative surgical site infection.

5. According to the National Nosocomial Infection Surveillance System, which one of the following organisms is *most often* isolated from surgical site infections?

A. *Streptococcus pneumonia*

B. *Staphylococcus aureus*

C. *Escherichia coli*

D. *Enterococci* sp.

6. The Center for Disease Control recommends that vancomycin should be substituted for a cephalosporin for surgical prophylaxis when:

A. Methicillin-resistant *S. aureus* is suspected

B. "Contaminated" and “dirty” procedures are expected

C. Patients with a documented history of a life-threatening allergy to penicillins or cephalosporins.

D. The surgical procedure involves implantation of any prosthetic device.

E. A and C.

7. Which one of the following statements regarding prophylactic antimicrobial regimens is *false*?

A. Therapeutic antimicrobials for unrelated infections can be used in place of a prophylactic antimicrobial regimen, provided the antibiotic used has appropriate antimicrobial activity.

B. Bactericidal concentrations of antibiotics must be delivered to the surgical site prior to the initial incision.

C. Bactericidal concentrations of antibiotics must be maintained throughout the duration of the surgery.

D. Antimicrobials should be administered with anesthesia or within 60 minutes prior to the initial incision.

8. Intraoperative redosing of antimicrobials are required for surgical procedures longer than:

   A. 5 half-lives of the antibiotic used for prophylaxis

   B. 2 hours

   C. 2.5 half-lives of the antibiotic used for prophylaxis

   D. 6 hours

9. With respect to gastrointestinal surgeries, third-generation cephalosporins are considered to be effective prophylactic regimens for:

   A. Cholecystectomies

   B. Gastroduodenal surgeries

   C. Colorectal surgeries

   D. All of the above

10. Regarding colorectal surgery, which one of the following statements is *true*?

   A. Mechanical bowel preparation (ie, with polyethylene glycol) is an effective way to reduce bacterial load in the colon.

   B. Most surgeons report routinely using a mechanical bowel preparation in addition to antibiotics prior to elective colorectal surgery.

   C. Mechanical bowel preparation (ie, with polyethylene glycol) is an effective way to reduce surgical site infection risk after elective colorectal surgery.

   D. All of the above.

   E. A and B only.

11. Prophylactic antimicrobial therapy for gastrointestinal endoscopy is recommended for:

   A. All patients as postprocedure bacteremia is common

   B. No patient as the risk of postprocedure infection is low

   C. High-risk procedures including colonoscopy

   D. High-risk patients including those with prosthetic heart valves

12. Which one of the following statements about hysterectomies is *false*?

   A. Cefazolin is the prophylactic drug of choice for vaginal hysterectomies.

   B. Abdominal hysterectomies are associated with a higher rate of surgical site infections when compared to vaginal hysterectomies.

   C. It is unnecessary to provide more than 24 hours of prophylactic antimicrobial coverage for abdominal hysterectomies.

   D. Metronidazole is a reasonable alternative to a cephalosporin for penicillin-allergic patients undergoing a hysterectomy.

13. Screening and preoperative eradication of *S. aureus* with intranasal mupirocin and chlorhexidine body wash has been shown to reduce surgical site infections:

   A. Only in cardiac surgery

   B. Only in orthopedic surgery

   C. Only in neurosurgery

   D. Both cardiac and orthopedic surgeries

14. Patients suffering an open compound limb fracture:

   A. Requires no more than 24 hours of prophylactic antibiotics

   B. Requires no more than a single dose of prophylactic antibiotics

   C. Requires a course of antibiotics for "presumptive" infection

   D. None of the above

15. Non-antimicrobial strategies to reduce surgical site infections include all of the following, except:

   A. Permissive hypothermia intraoperatively

   B. High concentrations of oxygen administration intraoperatively

   C. Protocolized aseptic technique

   D. Perioperative normoglycemia

SELF-ASSESSMENT QUESTION-ANSWERS

1. **C.** For a patient with acute cholecystitis that requires surgical intervention one must presume that the surgical site is contaminated, and the risk of active infection is high. Therefore, a presumptive course of antimicrobials is warranted. If culture results or diagnostic imaging confirm an active infection, then therapeutic (and culture directed) antimicrobial therapy would be warranted.

2. **A.** Clean procedures have the lowest relative risk of postoperative surgical site infections and typically do not require prophylactic antimicrobials.

3. **C.** Unlike gender, smoking history, nutritional status, and diabetes have all been identified as risk factors for surgical site infections.

4. **D.** Although malnutrition has been identified as a risk factor for surgical site infections, perioperative dietary supplementation has not been shown to reduce this risk.

5. **B.** Skin flora is the most common source of wound and surgical site bacterial contamination and staphylococcal species are the most common bacterial pathogens found in skin flora.

6. **E.** Beta-lactam antibiotics are the preferred agents for surgical site infection prevention unless resistant gram-positive organisms are suspected (ie, methicillin-resistant *S. aureus*) or the patient has a documented and serious allergy to penicillins or cephalosporins. Understanding resistance patterns at your institution will help assess this risk related to resistant organisms.

7. **A.** Therapeutic antimicrobials for unrelated indications should not be relied upon for surgical prophylaxis even if their spectrum of bacterial coverage would be sufficient for surgical prophylaxis. Issues of dose and timing of administration are critical to the efficacy of surgical prophylaxis. Prophylactic antimicrobials should ideally be administered within 60 minutes prior to the initial incision. It is more practical to schedule the prophylactic antibiotic prior to the surgery than to schedule the surgery according to the administration times of the therapeutic antimicrobial regimen.

8. **C.** Because different prophylactic antimicrobials are indicated for different surgical procedures it makes more sense to consider the duration of therapeutic serum concentrations at the site of the infection rather than an arbitrary or absolute time trigger. This is best estimated using the half-

life of the antimicrobial. At 2.5 half-lives serum concentrations will have dropped more than 80% from baseline and should be the trigger for redosing.

9. **C.** Compared with first- and second-generation cephalosporins, third-generation cephalosporins have increased activity against gram-negative organisms including most pathogenic enteric gram negatives. The risk of surgical site infections caused by gram-negative organisms is higher with colorectal surgeries than gastroduodenal procedures or cholecystectomies and thus warrant better gram-negative coverage with third-generation cephalosporins.

10. **E.** Despite the widespread use of mechanical bowel preparations prior to colorectal surgery they have never been shown to reduce the risk of surgical site infections. They do, however, reduce bacterial load in the colon and allow for easier bowel manipulation and instrumentation.

11. **D.** Prophylactic antimicrobials for gastrointestinal endoscopy is only indicated for high-risk patients, including those with prosthetic heart valves.

12. **B.** Vaginal hysterectomies are associated with a greater risk of surgical site infections when compared to abdominal hysterectomies because of the polymicrobial flora and risk of contamination at the surgical site.

13. **D.** Preoperative attempts to eradicate *S. aureus* from the skin and nares to reduce surgical site infections has only been shown to be effective in orthopedic and cardiac surgery.

14. **C.** The risk of direct contamination and subsequent surgical site infections after repair of an open compound limb fracture is significantly higher than that of a closed fracture. Therefore in these cases infection should be presumed.

15. **A.** Intraoperative hypothermia should be avoided when possible as this has been shown to increase the risk of surgical site infections.

DiPiro: Pharmacotherapy A Pathophysiologic Approach, 12e

Chapter 147: Vaccines and Immunoglobulins

Mary S. Hayney

KEY CONCEPTS

KEY CONCEPTS

1. Live vaccines may confer life-long immunity but cannot be administered to immunosuppressed patients.

2. Inactivated and subunit vaccines and toxoids often require multiple doses to protect from infection, and generally booster doses are needed following the primary series.

3. Children less than 2 years of age are unable to mount T-cell–independent immune responses that are elicited by polysaccharide vaccines.

4. Severely immunocompromised individuals should not receive live vaccines, and their responses to inactivated, polysaccharide, toxoid, and recombinant vaccines may be poor.

5. The childhood and adult immunization schedules are updated frequently and published annually. These documents can be used to develop an immunization plan.

6. Immunoglobulin (Ig) provides short-term, rapid postexposure protection from measles, hepatitis A, varicella, and other infections.

7. Ig adverse effects are often secondary to infusion rate. Slowing the IV infusion rate ameliorate chills, nausea, and fever that may develop during administration.

8. Rh_o(D) Ig prevents Rh-negative mothers from mounting an immune response against the Rh(D) antigen on the red blood cells of the fetus that results in hemolytic disease of the newborn.

BEYOND THE BOOK

Devise immunization recommendations for the below mentioned cases.

1. A 56-year-old male with newly diagnosed type 2 diabetes who has not received any vaccines in the past 12 years.
2. A 26-year-old patient who was fully immunized prior to kidney transplant 6 years ago.
3. A 52-year-old male who smokes a pack of cigarettes every day and has not received any vaccines as an adult.

Use the immunization schedules found at https://www.cdc.gov/vaccines/schedules

INTRODUCTION

Immunization provides protection from infectious diseases. Immunity to an infectious agent can be acquired by exposure to the disease, by transfer of antibodies from mother to fetus, through administration of immunoglobulin (Ig), and from vaccination. Immunization is the process of introducing an antigen into the body to induce protection against the infectious agent without causing disease. An *antigen* is a substance that induces an immune response. An *antibody* produced by the humoral arm of the immune system usually is the response that is measured as evidence of successful vaccination. However, cellular immune responses, which are more difficult to measure, are also an important aspect of vaccine responses. This chapter introduces the clinical use of vaccines and immunoglobulins. Agents with a limited use, such as agents for bioterrorism or travel, are beyond the scope of this chapter.

PRODUCTS USED TO IMMUNIZE

① ② ③ Vaccines induce active immunity—that is, immunity generated by a natural immunologic response to an antigen. Vaccines can be live-attenuated or inactivated. Inactivated vaccines may consist of whole or part of the pathogen that induces a protective immune response. Live-attenuated vaccines induce an immunologic response similar to that occurring with natural infection. Because the organisms in live-attenuated vaccines undergo limited replication in the vaccinated individual after administration, they may confer lifelong immunity with one dose (as does a natural infection). Viral vector vaccines are transfected with the gene for the antigen to which immunization is desired. The viral vector which can be further engineered to not replicate, is just the carrier for the gene. The viral vector enters the cell inducing an immune response to the target infection when the inserted gene is expressed during the course of the "infection." With an mRNA vaccine, the mRNA is protected by a liposome from degradation and facilitates its entry into cells, then uses cellular machinery to transcribe the mRNA. Following transcription, the antigen is expressed as a protein on the cell surface which initiates an immune response. Multiple doses of inactivated vaccines usually are needed to induce long-lasting, effective immunity. Additional doses at varying time intervals (booster doses) often are required to maintain immunity. Booster doses of such vaccines elicit memory responses from the B cells that produce immunoglobulin G (IgG). The immune system already has developed an array of antibodies to the antigen. Upon restimulation with a booster dose, the B cells, which produce the most specific antibodies against the antigen, are selected and maintained in the "immunologic memory." Thus, the booster dose results in a rapid, intense antibody response that is long-lasting. Inactivated vaccines can also differ in immunity potential, depending on their composition. For example, polysaccharide vaccines tend to be poorly immunogenic in infants, whereas protein–polysaccharide conjugated vaccines of the same antigen tend to be highly immunogenic (eg, pneumococcal polysaccharide vaccine vs pneumococcal conjugated vaccine). T-cell–independent immune response is made to polysaccharide antigens that stimulate B cells directly.[1] There is no maturation or booster response with a T-cell–independent immune response, and children younger than 2 years cannot make this type of response. Protein–polysaccharide conjugate vaccines stimulate T cells and promote interactions between T cells and B cells when producing the protective immune responses consisting of immunologic memory and high-affinity IgG. Toxoids are inactivated bacterial toxins that stimulate the production of antibodies against the bacterial toxins rather than the infecting bacterial pathogens.

Immunoglobulins (Igs) are sterile solutions containing antibody derived from human (Ig) sources. Igs are derived from donor pools of blood plasma and are processed using cold ethanol fractionation in order to inactivate known potential pathogens. These products are indicated for induction of passive immunity (temporary immunity to infection as a result of administration of antibodies not produced by the host; see other immunoglobulins below).

In addition to the active component in a vaccine, other active and inert ingredients are often present. Some inactivated vaccines contain adjuvants which are chemicals that stimulate a strong, but short-lived inflammatory response which strengthens the immune response to the antigen. These adjuvants also increase local tissue irritation when injected. Suspending agents, such as water, saline, or complex fluids containing proteins (eg, albumin), are used as the vehicle for the vaccines. Preservatives, stabilizers, and antibiotics may be added to help maintain the integrity of the product. Immunized individuals may respond with allergic reactions not to the agent itself but to the other components of the pharmaceutical preparation. Different manufacturers of the vaccines have different active and inert ingredients or different quantities of these ingredients in their products.

Some vaccines manufactured by different companies are considered interchangeable. Hepatitis A, hepatitis B, and *Haemophilus influenzae* type b (Hib) conjugate vaccines from different manufacturers used for the primary series of three doses are considered interchangeable. It is preferable to use diphtheria, tetanus toxoids, and acellular pertussis (DTaP) vaccine from the same manufacturer to complete the entire primary series. However, immunization should not be delayed if the particular type of vaccine administered for the initial doses cannot be ascertained easily or the vaccine provider does not have the product available.[1]

FACTORS AFFECTING RESPONSE TO IMMUNIZATION

Various factors are known to affect response to vaccines. Viability of the live antigen is an important factor as discussed previously. Total dose also is important because there seems to exist a threshold dose above which no further increase in immune response is seen. The interval between immunization doses, number of doses given, or both may change immune response to an agent. Among hepatitis B vaccine nonresponders, a significant proportion of individuals mount a vaccine response when given additional doses of vaccine.[2] In contrast, additional doses of influenza vaccine are minimally effective in individuals with chronic illness.[3] Generally, intervals longer than those recommended between vaccine doses do not affect immune response.[1]

The route and site of administration of the immunobiologic are important. This is best illustrated by the hepatitis B vaccine, which elicits a satisfactory antibody response when given in the deltoid muscle but not a consistent response when administered in the gluteal area. Injections should be administered at a site with little likelihood of site damage. Vaccines containing adjuvants should be given into a muscle mass because they can cause irritation when given subcutaneously or intradermally.[1]

Host factors influence vaccine response. Immunocompromise, increasing age, underlying disease, and genetic background have been associated with poor response rates.[1–6]

VACCINE ADMINISTRATION

Subcutaneous injections should be administered into the thigh of infants and in the upper arm area over the triceps of older children and adults. A ⅝-in., 25-gauge needle (0.508 mm × 1.6 cm) should be used, taking care not to administer the dose intradermally or intramuscularly (IM). For IM injection, the anterolateral aspect of the upper thigh (infants and toddlers) or the deltoid muscle of the upper arm (children and adults) should be used. Appropriate needle size and length are important to both vaccine immune response and safety (Table 147-1). The buttock should not be used because of the potential for inadequate immunologic response and the potential risk of injury to the sciatic nerve. When the buttock must be used (as for large doses of Ig), only the upper outer quadrant should be used with the needle inserted anteriorly.

The rotavirus vaccines are administered orally. The tube of vaccine should be squeezed inside the infant's mouth toward the inner cheek until the dosing tube is empty. If the infant regurgitates or spits out the vaccine, readministration is not recommended.[7]

TABLE 147-1

Needle Length and Injection Site for Intramuscular Vaccine Administration

Age Group	Needle Length	Injection Site
Neonates (0-28 days)	5/8 in. (16 mm)[a]	Anterolateral thigh
Infants (1-12 months)	1 in. (25 mm)	Anterolateral thigh
Toddlers (1-2 years)	1-1.25 in. (25-32 mm)	Anterolateral thigh[b]
	5/8-1 in. (16-25 mm)	Deltoid muscle
Children (3-10 years)	5/8-1 in. (16-25 mm)	Deltoid muscle[b]
	1-1.25 in. (25-32 mm)	Anterolateral thigh
Children (11-18 years)	5/8-1 in. (16-25 mm)	Deltoid muscle[b]
	1-1.5 in. (25-38 mm)	Anterolateral thigh
Adults (>19 years)		
Men and women <60 kg (130 lb)	1 in. (25 mm)[c]	Deltoid muscle
Men 70-118 kg (152-260 lb)	1-1.5 in. (25-38 mm)	Deltoid muscle
Women 70-90 kg (152-200 lb)		
Men >118 kg (260 lb)	1.5 in. (38 mm)	Deltoid muscle
Women >90 kg (200 lb)		

[a] Skin should be stretched without bunching of subcutaneous tissue.

[b] This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of Ig or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an Ig preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an Ig preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

[c] Some experts recommend 5/8 in. (16 mm) needle, but skin must be stretched without bunching of subcutaneous tissue.

Adapted from Kroger A, Bahta L, Hunter P. General Best Practice Guidelines for Immunization. Best Practices Guidance of the Advisory Committee on Immunization Practices (ACIP).

Live-attenuated influenza vaccine is administered intranasally.[3] A specially designed sprayer is inserted just inside the nostril, and the dose is sprayed by rapidly depressing the plunger of the sprayer. The clip is removed from the plunger so that the second half of the dose can be administered into the other nostril. The vaccinated individual should breathe normally. The dose does not need to be repeated if the individual sneezes during or shortly after administration.

Questions often arise concerning the simultaneous administration of vaccines. In general, inactivated and live-attenuated vaccines can be administered simultaneously at separate sites. If two or more inactivated vaccines cannot be administered simultaneously, they can be administered without regard to spacing between doses. Inactivated and live vaccines can be administered simultaneously or, if they cannot be administered simultaneously, at any interval between doses. If live vaccines are not administered simultaneously, their administration should be separated by at least 4 weeks. Live viral vaccines may interfere with purified protein derivative response; thus, tuberculin testing should be postponed for 4 to 6 weeks after administration of live-virus vaccine.[1]

Simultaneous administration of Ig and live-attenuated vaccines may interfere with host antibody response. A dose relationship exists between administration of Ig and inhibition of immune response to a vaccine (Table 147-2). Whole blood and other blood products containing antibodies may interfere with the response to the measles, mumps, rubella, and varicella (MMRV) vaccines. In any individual, if vaccination with MMR or varicella is followed by emergency Ig administration, the vaccine can be repeated or seroconversion to viral antigens can be confirmed after sufficient time has elapsed (see Table 147-2). Ig does not interfere with the response to oral vaccines. Inactivated vaccines and Igs may be administered simultaneously using separate anatomical sites.[1]

TABLE 147-2

Recommended Intervals Between Administration of Immunoglobulin and Measles- or Varicella-Containing Vaccine[a]

Product/Indication	Dose, Including mg Immunoglobulin G(IgG)/kg Body Weight	Recommended interval before measles or varicella-containing[b] vaccine administration
RSV monoclonal antibody (Synagis®)[c]	15 mg/kg IM	None
TIG	250 units (10 mg IgG/kg) IM	3 months
Hepatitis A IG		
Contact prophylaxis	0.02 mL/kg (3.3 mg IgG/kg) IM	3 months
International travel	0.06 mL/kg (10 mg IgG/kg) IM	3 months
HBIG	0.06 mL/kg (10 mg IgG/kg) IM	3 months
RIG	20 IU/kg (22 mg IgG/kg) IM	4 months
Measles prophylaxis IG		
Standard (ie, nonimmunocompromised) contact	0.5 mL/kg (40 mg IgG/kg) IM	6 months
Blood transfusion		
RBCs, washed	10 mL/kg negligible IgG/kg IV	None
RBCs, adenine-saline added	10 mL/kg (10 mg IgG/kg) IV	3 months

Packed RBCs (Hct 65%) [0.65][d]	10 mL/kg (60 mg IgG/kg) IV	6 months
Whole blood (Hct 35%-50%) (0.35-0.50)[d]	10 mL/kg (80-100 mg IgG/kg) IV	6 months
Plasma/platelet products	10 mL/kg (160 mg IgG/kg) IV	7 months
Cytomegalovirus IV immunoglobulin (IGIV)	150 mg/kg maximum	6 months
IVIG		
Replacement therapy for immune deficiencies[e]	300-400 mg/kg Iv[d]	8 months
Immune thrombocytopenic purpura treatment	400 mg/kg IV	8 months
Immune thrombocytopenic purpura treatment	1 g/kg IV	10 months
Postexposure varicella prophylaxis[f]	400 mg/kg IV	8 months
Varicella IG	125 units/kg (60-200 mg IgG/kg) IM maximum 625 units	5 months

HBIG, Hepatitis B IG; RBCs, Red blood cells; RIG, Rabies IG; TIG, Tetanus IG.

[a] This table is not intended for determining the correct indications and dosages for using antibody-containing products. Unvaccinated persons might not be fully protected against measles during the entire recommended interval, and additional doses of Ig or measles vaccine might be indicated after measles exposure. Concentrations of measles antibody in an Ig preparation can vary by manufacturer's lot. Rates of antibody clearance after receipt of an Ig preparation also might vary. Recommended intervals are extrapolated from an estimated half-life of 30 days for passively acquired antibody and an observed interference with the immune response to measles vaccine for 5 months after a dose of 80 mg IgG/kg.

[b] Varicella-containing vaccine, as used here, does not include zoster vaccine. Zoster vaccine may be given without regard to antibody-containing blood products.

[c] Contains antibody only to respiratory syncytial virus (RSV).

[d] Assumes a serum IgG concentration of 16 mg/mL (g/L).

[e] Measles and varicella vaccinations are recommended for children with asymptomatic or mildly symptomatic human immunodeficiency virus (HIV) infection but are contraindicated for persons with severe immunosuppression from HIV or any other immunosuppressive disorder.

VACCINE STORAGE

Appropriate storage is critical to maintaining the integrity of vaccines. Refrigerator temperature is defined as between 2°C and 8°C (36°F to 46°F) and freezer temperature as 50°C (–58°F) to –15°C (5°F). Inactivated vaccines are stored refrigerated. Varicella and COVID-19 (Moderna) vaccine must be stored frozen. MMR vaccine can be stored in either the freezer or refrigerator. The Pfizer COVID-19 vaccine requires ultra-cold temperatures (–80°C to –60°C; –112°F to –76°F) for long-term storage. Live-attenuated influenza vaccine is stored in the refrigerator. Specific storage conditions for individual vaccines can be found in the package insert.

IMMUNIZATION OF SPECIAL POPULATIONS

Groups of individuals may have precautions to vaccines. Many precautions are temporary, and vaccines can be administered later.

Infants

The age of the recipient is an important determining factor in vaccine response. In the first few months of life, passively transferred maternal antibodies acquired during the third trimester of gestation protect an infant. However, the maternal antibodies also inhibit the immune response to live vaccines because the circulating antibodies neutralize the vaccine before the infant has the opportunity to mount an immune response. For this reason, MMRV vaccines are not administered until maternal antibodies have waned, generally by infant age 12 months.

Premature infants should be vaccinated at the same chronologic age using the same schedule and precautions for full-term infants. The full recommended doses of vaccines should be used, regardless of age or birth weight. Breastfed infants should be vaccinated according to standard pediatric schedules.

Pregnant Women and Postpartum Immunization

The benefit of most vaccines outweighs the risk for administration to those who are pregnant. As with most drugs, a lack of information regarding risks to the fetus exists rather than any actual known risk.[1] For example, no cases of congenital rubella syndrome from inadvertent administration of rubella vaccine to a pregnant person have ever been reported. Universal influenza immunization is recommended for individuals who will be or are pregnant during influenza season. Tdap should be administered during the late second trimester or third trimester of pregnancy.[8] Although live vaccines generally are avoided because of the theoretical risk of transmission of the vaccine organism to the fetus, inactivated vaccines may be administered when the benefits outweigh the risks.[1] Insufficient evidence is available for the human papillomavirus (HPV) series during pregnancy, so it should be deferred.[1]

Administration of live vaccines, such as rubella or varicella, are deferred until pregnancy is completed and are routinely recommended for those who do not have evidence of immunity prior to hospital discharge. These live vaccines can be administered without regard to administration of Rh_o(D) Ig in the postpartum period. Additionally, Tdap is recommended for all new mothers who have not received a Tdap before because household contacts are frequently implicated as the source of pertussis infection in a young infant.[8]

Immunocompromised Hosts

④ Immunization of individuals with chronic disease, such as immunocompromise, diabetes or connective tissue disease, alcoholism, or those with cancer or HIV disease, must be individualized based on the disease state and its treatment. In general, severely immunocompromised individuals should not receive live vaccines. Administration of other vaccines may be indicated, but responses may be lower than those mounted by healthy individuals, but may still confer protection.[4]

Patients with chronic pulmonary, renal, hepatic, or metabolic disease who are not receiving immunosuppressants can receive both live-attenuated and killed vaccines and toxoids. Generally, immunization should be considered early in the course of the disease in an attempt to induce immunity at a point when the disease is less severe.

Patients with active malignant disease can receive killed vaccines or toxoids but should not be given live vaccines. The MMR vaccine is not contraindicated for close contacts, however. Live-virus vaccines can be administered to persons with leukemia who have not received chemotherapy for at least 3 months. Vaccines should be timed so that they do not coincide with the start of chemotherapy or radiation therapy.[3] Annual influenza vaccine should be administered 2 weeks prior to chemotherapy or between cycles.[3] If vaccines cannot be given at least 2 weeks before the start of these therapies, immunization should be postponed until 3 months after the therapy has been completed. Passive immunization with Ig can be used in place of active immunization regardless of the history of immunization.

Glucocorticoids may cause suppressed responses to vaccines. For the purposes of immunization, the immunosuppressing dose of corticosteroids is prednisone 20 mg or more daily or 2 mg/kg daily, or an equivalent dose of another steroid, for at least 2 weeks. Patients receiving long-term, alternate-day steroid therapy with short-acting agents, administration of maintenance physiologic doses of steroids (eg, 5-10 mg/day of prednisone) topical, aerosol, intra-articular, bursal, or tendon steroid injections require no special consideration for immunization. If patients have been receiving high-dose corticosteroids or have had a course lasting longer than 2 weeks, then at least 1 month should pass before immunization with live-virus vaccines.[1]

Patients with HIV infection may have suboptimal immune responses to live and inactivated vaccines. The routinely recommended vaccines should be administered to children. MMR should be administered to anyone older than 12 months of age without evidence of immunity and who are not severely immunocompromised (CD4% greater than 15% [or CD4 fraction >0.15] and CD4 count greater than 200 lymphocytes/mm^3 [0.2 × 10^9/L] for at least 6 months) and repeat MMR series should be considered if vaccinated prior to initiation of combination antiretroviral therapy.[9] Two doses of varicella vaccine separated by 3 months are recommended for those with no evidence of immunosuppression. Adults should receive routinely recommended vaccines. Zoster vaccine may be administered to individuals with HIV infection who do not have clinical manifestations of AIDS and have CD4 counts greater than 200/mm^3 (0.2 × 10^9/L).[1]

Solid Organ Transplant Patients

Organ transplantation has become routine treatment of end-stage organ disease of many causes. Solid organ transplant patients remain on immunosuppressive regimens for the rest of their lives. These immunosuppressive regimens result in a higher risk of infection and decrease the protection conferred by immunization.[10]

Whenever possible, transplant patients should be immunized prior to transplantation. Live vaccines generally are not given after transplantation. Posttransplantation diphtheria, tetanus, pneumococcal, and influenza vaccine responses are unpredictable. Decreased immune response has been documented following hepatitis B vaccine series.

Patients with Hematopoietic Stem Cell Transplant

Patients with hematopoietic stem cell transplantation receive therapy that almost eliminates hematopoietic cells and may require immunosuppressive medications post-transplant for graft-versus-host disease. Therefore, reimmunization with inactivated vaccines should begin approximately 6 months after hematopoietic stem cell transplantation. Annual influenza immunization may begin as soon as 6 months after successful engraftment. Hematopoietic stem cell transplant recipients are at increased risk for fulminant infection with encapsulated bacteria, so 13-valent pneumococcal vaccine (PCV13), the 23-valent pneumococcal polysaccharide vaccine (PPSV23), meningococcal vaccines, and Hib vaccines are recommended. MMR and varicella vaccines can be administered at 24 months. Immunization of household contacts and healthcare workers also is necessary.[1,11]

CONTRAINDICATIONS AND PRECAUTIONS

There are few contraindications to the use of vaccines except those outlined earlier. The contraindications include a history of anaphylactic reactions to the vaccine or a component of the vaccine. Unexplained encephalopathy occurring within 7 days of a dose of pertussis vaccine is a contraindication to future doses of pertussis vaccines. Immunosuppression and pregnancy are temporary contraindications to live vaccines. An interval of time must elapse based on the dose of Ig before a live vaccine can be administered (see Table 147-2). A personal or family history of seizures is a precaution for receiving the combination MMR–varicella (MMRV) vaccine. Immunizers should use MMR and varicella vaccines separately.[1] Generally, mild-to-moderate local reactions, mild acute illnesses, concurrent antibiotic use, prematurity, family history of adverse events, diarrhea, and lactation or breastfeeding are not contraindications to immunization.

OBTAINING AN IMMUNIZATION HISTORY

An immunization history should be obtained from every patient, regardless of the reason for the healthcare visit. State-based or other public health jurisdiction-based immunization information systems, also called immunization registries, have been developed to improve immunization coverage by allowing healthcare providers access to records at any contact with the healthcare system. If an official written record is not available, patient characteristics (eg, military service, travel history, and occupation) may provide clues to the immunization history. Serologic testing for immunity has a limited role in documenting immunization history but is done in selected circumstances (eg, employment in a healthcare facility). If a written record does not exist, one should be generated at the time of initiation of immunization. Patients without a written record should be considered susceptible, and an immunization program started and completed unless a serious adverse reaction occurs. As a general rule, the risks associated with overimmunization are minimal relative to the risks associated with contracting vaccine-preventable diseases.[1]

Every healthcare visit, regardless of its purpose, should be viewed as an opportunity to review a patient's immunization status and to administer needed vaccines. Immunization is perhaps the most cost-effective health intervention available. Each visit should include assessment of individuals' vaccine needs, administration of indicated vaccines, and documentation of immunization histories. The outcome measurement of what percentage of patients in a particular practice site is completely immunized is extremely important because the benefits of optimal vaccine use extend beyond the individual patient to the public as a whole.

VACCINE SAFETY

The United States has a robust vaccine safety monitoring system. Healthcare providers must report all events requiring medical attention within 30 days of vaccination to the Vaccine Adverse Event Reporting System (VAERS), which serves as a central depot for vaccine-related adverse effects. Only a temporal association between the adverse event and vaccine administration is required. No adverse event rates can be determined because only the number of adverse events reported is known; the number of vaccines administered is not known. This database can be used to survey for changes in the frequencies of adverse events, to evaluate risk factors for adverse events, and to find rare adverse events.[11] VAERS reports can be made online at https://vaers.hhs.gov/reportevent.html. In addition to VAERS, the Vaccine Safety Datalink connects the Centers for Disease Control and Prevention (CDC) and large healthcare systems to actively monitor vaccine safety, and the Clinical Immunization Safety Assessment Project is a partnership between the CDC and academic medical centers to provide expert consultation and conduct research on vaccine safety.[13] The Institute of Medicine is an independent body that studies and reports on vaccine safety.[14]

The National Childhood Vaccine Injury Act of 1986 offers a no-fault alternative means to compensate individuals for injury following vaccination. The program offers liability protection to manufacturers and an efficient means of recovering damages for individuals potentially injured by vaccines. The types of vaccine-related injuries that are considered for compensation are outlined in the Health Resources and Services Administration's Vaccine Injury table (https://vaers.hhs.gov/docs/VAERS_Table_of_Reportable_Events_Following_Vaccination.pdf).

USE OF VACCINES

The Advisory Committee on Immunization Practices (ACIP) is composed of medical and public health experts who make recommendations for vaccine use.[15] They consider burden of disease, vaccine efficacy and safety, and cost effectiveness of vaccines. Other professional organizations, for example, the American Academy of Pediatrics, the American Academy of Family Physicians, or the American College of Obstetrics and Gynecology, publish guidelines. Usually, these guidelines are the same as those issued by the ACIP or the groups try to reconcile their recommendations.

⑤ The latest vaccine schedules can be found at https://www.cdc.gov/vaccines/schedules/hcp/index.html. All states require children to be fully immunized prior to entering elementary school; however, optimal protection is achieved by immunizing at the recommended ages, which requires special attention to children younger than 2 years. Adults and adolescents also require vaccination and often are unaware of this need. An early adolescent preventive health visit at age 11 to 12 years is recommended. This visit is an opportunity to catch up on missed immunizations and to administer meningococcal conjugate, Tdap, and HPV vaccines. Additionally, another visit at age 16 is recommended during which time the second meningococcal conjugate vaccine can be administered and a discussion regarding the need for meningococcal serogroup B vaccine series can occur. All individuals older than 6 months of age should receive an annual seasonal influenza vaccine. Adults should receive routine tetanus–diphtheria (Td) or Tdap boosters and be immune to MMRV by either immunization or history of infection. Adults need zoster vaccine after age 50 years, and pneumococcal vaccines after age 65 years. Certain individuals with conditions or lifestyles that put them at high risk for vaccine-preventable diseases also should be immunized as described in the following text and outlined in the immunization schedules in the appendices.

VACCINES

Diphtheria Toxoid Adsorbed

Diphtheria is an acute illness caused by the toxin released by a *Corynebacterium diphtheriae* infection. The toxin inhibits cellular protein synthesis, and membranes form on mucosal surfaces. Systemic toxemia can result in myocarditis, neuritis, and thrombocytopenia. Membrane formation can cause respiratory obstruction, and significant toxin absorption can lead to severe illness and death.

Diphtheria toxoid adsorbed is a sterile suspension of modified toxins of *C. diphtheriae* that induces immunity against the exotoxin of this organism. Two strengths of diphtheria toxoid are available in the United States: pediatric strength (D) and adult strength (d), which contains less antigen. The widespread use of diphtheria toxoid essentially has eliminated diphtheria from the United States.

Primary immunization with diphtheria toxoid (D) is indicated for children older than 6 weeks. The toxoid is given in combination with tetanus toxoid and acellular pertussis vaccine (as DTaP or in combination with additional childhood vaccines that have been licensed to decrease the number of injections required to complete the childhood immunization recommendations) at age 2, 4, and 6 months. Additional doses are given at age 15 to 18 months and again at age 4 to 6 years.[8] Booster doses should be given every 10 years.

For unimmunized adults, a complete three-dose series of diphtheria toxoid should be administered, with the first two doses given at least 4 weeks apart and the third dose given 6 to 12 months after the second. One of the vaccine doses in this series should be Tdap. The combined Td preparation is used for adults because it contains less diphtheria toxoid than the pediatric dose and is associated with fewer reactions to the diphtheria component. All adults should receive booster doses of Td or Tdap every 10 years.[8] Adverse effects of diphtheria toxoid include mild-to-moderate tenderness, erythema, and induration at the injection site. Systemic reactions occur rarely.

Haemophilus Influenzae Type b Vaccines

Before 1995, Hib was responsible for thousands of cases of serious illnesses (eg, meningitis, epiglottitis, pneumonia, sepsis, and septic arthritis). The incidence of Hib disease has declined more than 99% since the introduction of the conjugate vaccines based on the organism's capsular substance, polyribosylribitol phosphate (PRP).[16]

Hib conjugate vaccines are indicated for routine use in all infants and children younger than 5 years. Multiple products in various combinations are available for use in infants and children of different ages. The primary series of Hib vaccination consists of a 0.5-mL IM dose at ages 2, 4, and 6 months. The series should not be initiated in an infant younger than 6 weeks. Although use of one product for the entire primary series is desirable, adequate protection is achieved even when different products are used during the initial series. Following the primary series, a booster dose is recommended at age 12 to 15 months. Any of the Hib conjugate vaccines are suitable for the booster dose regardless of which conjugate was used for the primary series of doses.[16]

Schedules are more complex for infants who do not begin Hib immunization at the recommended age or who have fallen behind in the immunization schedule. For infants 7 to 11 months of age who have not been vaccinated, three doses of Hib vaccine should be given: two doses spaced 4 weeks apart and then a booster dose at age 12 to 15 months (but at least 8 weeks since the second dose). For unvaccinated children ages 12 to 14 months, two doses should be given, with an interval of 2 months between doses. In a child older than 15 months, a single dose of any of the vaccine preparations is indicated.[16]

Vaccines for Hib are recommended for routine use only for children up to age 59 months; beyond this age, the incidence of invasive Hib disease is low. Patients with certain underlying conditions (eg, children with HIV infection, sickle cell disease, splenectomy, and hematopoietic stem cell transplants and young children receiving chemotherapy for malignancies) are at higher than normal risk for Hib infection, and use of at least one dose of vaccine in these patients should be considered.[16] Adverse reactions to the Hib vaccine are uncommon. Erythema and induration at the injection site occur in approximately 5% to 30% of children and resolve within 12 to 24 hours. Fever, diarrhea, and vomiting are reported occasionally.[16]

Hepatitis Vaccines

Information on vaccination for viral hepatitis is given in Chapter 58.

Human Papillomavirus Vaccine

HPV infections are the most common sexually transmitted infections, with the highest prevalence of infection in sexually active young adults. Although more than 120 different HPV types have been identified, at least 40 different types of HPV infect the anogenital tract. These 40 different viruses are grouped into low-risk and high-risk types. Low-risk types can cause genital warts and mild abnormalities on Papanicolaou (Pap) tests. Ninety percent of all cases of genital warts and the majority of respiratory papillomatosis are caused by types 6 and 11. As many as 18 types are considered high risk as they have the ability to penetrate the nucleus of an epithelial cell to transform it to a precancerous cell. They cause abnormal Pap test results and may lead to cancer of the cervix, vulva, vagina, anus, penis, or oropharynx. Types 16 and 18 cause about 70% of all cervical cancers. Another 10% of HPV-related cancers are caused by types 31, 33, 45, 52, and 58. Men who have sex with men (MSM) are at a higher risk for infection with HPV, genital warts, and anal cancer.[17] The incidence of cancers associated with HPV is higher among MSM, and the rate of anal cancer among MSM continues to rise. High-risk HPV infections are necessary but not sufficient for the development of cervical cancer and for the majority of other anogenital and oral squamous cell cancers.

A 9-valent HPV vaccine against types 6 and 11 and 16, 18, 31, 33, 45, 52, and 58 is licensed for the prevention of HPV. ACIP recommends HPV vaccine for the prevention of HPV-related disease in individuals aged 9 to 26 years. Individuals who start the HPV series between the ages of 9 and 14 years should receive two doses separated by 6 months. This vaccine is administered as a three-dose series using a schedule of 0, 1 to 2, and 6 months for individuals who start the series at age 15 years or older. The vaccines are recommended for adolescents aged 11 to 12 years and catch-up immunization for individuals aged 13 to 26 years. The ACIP recommended shared clinical decision making for HPV vaccine for individuals aged 27 to 45 years.[17]

The vaccine is well tolerated, with injection-site reactions and systemic reactions (eg, headache and fatigue) occurring as commonly in immunized individuals as in the groups receiving placebo. Although syncope is possible with any immunization, the target population of adolescents and young adults has a higher incidence of syncope, including with administration of the HPV vaccine.[17]

Influenza Virus Vaccine

Information on vaccination for influenza is given in Chapter 131.

Measles Vaccine

Measles (rubeola) is a highly contagious viral illness characterized by rash and high fever. Complications of measles infections include severe diarrhea, otitis media, pneumonia, and encephalitis. Measles results in one to two deaths per 1,000 cases, with a much higher death rate in developing countries. With widespread vaccination, measles has been eliminated from the Western Hemisphere.

The measles vaccine is a live-attenuated viral vaccine that produces a subclinical, noncommunicable infection. Approximately 95% of vaccine recipients mount a protective immune response after a single dose, and most individuals are protected for life.[9] Most persons who do not respond to the first dose of measles vaccine will respond after receiving a second dose, and this forms the basis for the two-dose vaccine strategy that was implemented in the United States in 1989.

The measles vaccine is administered subcutaneously as a 0.5-mL dose in the arm (or in the thigh if the patient is younger than 15 months). The vaccine is administered routinely for primary immunization to persons 12 to 15 months of age. Two combinations of measles containing vaccines are available: measles, mumps, rubella (MMR) or measles, mumps, rubella, varicella (MMRV). The measles vaccine is not administered earlier than 12 months (except in certain outbreak circumstances or for travel) because persisting maternal antibody that was acquired transplacentally late in gestation can neutralize the vaccine virus before the vaccinated person can mount an immune response. A second dose of measles-containing vaccine is recommended when children are 4 to 6 years old.[9] The second dose of vaccine results in response in up to 99% of individuals.

Measles-containing vaccine should not be given to pregnant women or immunosuppressed patients. An exception is HIV-infected patients, who are at high risk for severe complications if they develop measles. Adults with HIV infection who have no evidence of measles immunity should be immunized as long as they are not severely immunocompromised (CD4 greater than 200 lymphocytes/mm^3 [0.2×10^9/L] for at least 6 months). The second dose should be given 1 month later.[8] Children with HIV who are not severely immunocompromised can be immunized according to the childhood immunization schedule at 12 months and 4 to 6 years of age.[9]

Administration of Ig interferes with measles vaccine response, so the recommended interval between the Ig and vaccine is determined by the dose of Ig (see Table 147-2).[1] Live vaccines not administered during the same visit must be delayed for at least 4 weeks following measles or MMR vaccine.[1]

Measles vaccine is indicated in all persons born after 1956 or in those who lack documentation of wild-virus infection by either history or antibody titers. Two doses of a measles-containing vaccine separated by at least one month are required for children, college students, and healthcare workers who were born in 1957 or later.[9]

The measles vaccine has an excellent safety record. The most common side effect following vaccination is fever, which occurs in 5% to 15% of vaccinees. Transient generalized rash may occur in approximately 5% of vaccine recipients. These reactions generally appear 5 to 12 days postvaccination and last 2 to 5 days. Other adverse effects, such as headache, cough, sore throat, eye pain, malaise, and transient thrombocytopenia, occur less frequently.[9]

Meningococcal Vaccines

N. meningitidis is a leading cause of meningitis and sepsis in children and young adults in the United States. Five serotypes, A, B, C, W-135, and Y, cause almost all infections in humans. The infection is transmitted by respiratory droplets from infected individuals and asymptomatic carriers. Symptoms include severe headache, sensitivity to light, stiff neck, nausea and vomiting, and high fever. Mortality occurs in 24 to 48 hours following onset of symptoms in 10% to 13% of infected individuals.[18] Immunization is recommended for high-risk populations, such as those exposed to the infection, those in the midst of uncontrolled outbreaks, travelers to areas with epidemic or hyperendemic meningococcal disease, and individuals who have terminal complement component deficiencies or asplenia.

MenACWY Conjugate

Two meningococcal (MenACWY) conjugate vaccines combining the same serotypes are licensed for use in individuals aged 9 months to 55 years old (Menactra®, Sanofi-Pasteur) or 2 months to 55 years old (Menveo®, Novartis).

The meningococcal conjugate vaccine is recommended for adolescents at ages 11 to 12 years with a second dose at age 16 years. Reimmunization at 5-year interval is recommended for individuals who are at high risk.[18]

Injection-site reactions are the most common adverse effects following administration of either the meningococcal conjugate or polysaccharide vaccine.

MenB vaccines

Meningococcal serogroup B (MenB) vaccines use recombinant antigens from the bacterial capsule, specifically factor H binding protein, Neisseria adhesin A, neisserial heparin binding antigen, and outer membrane vesicles. The ACIP recommends either of the two MenB vaccines, Trumenba® or Bexsero®, for individuals at high risk for invasive meningococcal disease.[17] Additionally, MenB vaccine use should be considered through shared clinical decision-making for adolescents and young adults. Trumenba® requires two or three dose series administered at 0 and 6 months or 0, 2, and 6 month intervals. (The three-dose series should be used for high-risk individuals and during an outbreak.) Bexsero® requires two doses with at least one month between doses. Both vaccines were licensed based upon antibody response studies.[18] The most common adverse events after MenB vaccines are pain at the injection site, fatigue, headache, myalgia, and chills.

Mumps Vaccine

Mumps is a viral illness that classically causes bilateral parotitis 16 to 18 days after exposure. Fever, headache, malaise, myalgia, and anorexia may precede the parotitis. Serious complications are rare but more common in adults.

The mumps vaccine is a live-attenuated vaccine. The vaccine is available in combinations with measles, rubella (as MMR), and varicella (MMRV) vaccines.

The vaccine is administered as a 0.5-mL subcutaneous injection in the upper arm. Dosing recommendations coincide with those for measles vaccine, with the first dose administered at age 12 to 15 months and the second dose prior to the child's entry into elementary school. Two doses of mumps-containing vaccine are recommended for school-aged children, international travelers, students in post–high school educational institutions, and healthcare workers born after 1956.[9] A single dose of vaccine is acceptable documentation of immunity to mumps for other adults considered at lower risk of mumps infection, including adults born after 1956 and those with an uncertain history of wild-virus infection. Mumps vaccine should not be given to pregnant women or immunosuppressed patients.[1] A third dose of mumps vaccine should be considered for individuals at risk for infection during an outbreak.[19]

Serious adverse reactions to the vaccine are reported rarely. Fever, parotitis, rash, and lymphadenopathy occur rarely. Local reactions, including soreness, burning, and stinging, may occur at the injection site.[9]

Pertussis Vaccine

Pertussis is caused by a bacterial infection with *Bordetella pertussis*. The infection starts with signs and symptoms of an acute respiratory infection, called the catarrhal stage. The coughing spells manifest about a week later. Typically, young children will have the characteristic whoop as they struggle to inhale while coughing. Adolescents and adults are more likely to have prolonged periods of coughing. Pertussis can affect any age group, but young infants are at much higher risk for pneumonia, seizures, brain damage, and death. Their rate of hospitalization is much higher than for other age groups. The individual is contagious during the catarrhal stage and the first 2 weeks of the cough.[8]

Acellular pertussis vaccines contain components of the *B. pertussis* organism. All acellular vaccines contain pertussis toxin, and some contain one or more additional bacterial components (eg, filamentous hemagglutinin, pertactin, and fimbriae types 2 and 3). Acellular pertussis vaccine is recommended for all doses of the pertussis schedule at 2, 4, 6, and 15 to 18 months of age. A fifth dose of pertussis vaccine is given to children 4 to 6 years of age.[20] Pertussis vaccine is administered in combination with diphtheria and tetanus (DTaP). Administration of an acellular pertussis-containing vaccine (Tdap) is also recommended for adolescents once between ages 11 and 18 years and a single dose of Tdap should be administered to all adults.[19] Additional doses of acellular pertussis-containing vaccine for adults are acceptable, as the ACIP considers Td and Tdap interchangeable.[20] Special attention is warranted for the immunization of individuals who have close contact with young infants. Tdap should be administered to females in their late second or third trimester of pregnancy. Tdap should also be administered to all close contacts, including household contacts and out of home care providers.[8]

Local administration site reactions are relatively common. Systemic reactions, such as moderate fever, occur in 3% to 5% of vaccinees. Rarely, high fever, febrile seizures, persistent crying spells, and hypotonic hyporesponsive episodes occur following vaccination. Encephalopathy without known cause within 7 days of a pertussis vaccine are contraindications to future doses of this vaccine.[1]

Pneumococcal Vaccines

Streptococcus pneumoniae is a common pathogen with a range of manifestations, including asymptomatic upper respiratory tract colonization, sinusitis, acute otitis media, pharyngitis, pneumonia, meningitis, and bacteremia. Rates of invasive infections are highest in children younger than 2 years and in the elderly.[21,22] The majority of invasive pneumococcal infection deaths occur in the elderly or in those with underlying medical conditions. Two pneumococcal vaccine preparations, PCV13 and 23-valent pneumococcal polysaccharide vaccine (PPSV23) are available. The vaccines have different indications and are not interchangeable.

Pneumococcal Polysaccharide Vaccine

Pneumococcal polysaccharide vaccine (Pneumovax 23) is a mixture of highly purified capsular polysaccharides from 23 of the most prevalent or invasive types of *S. pneumoniae* seen in the United States. These 23 types represent 85% to 90% of all blood isolates and 85% of pneumococcal isolates from other generally sterile sites. The vaccine is administered IM or subcutaneously as a single 0.5-mL dose.

PPSV23 is recommended for the following individuals[23]:

1. Persons 65 years and older (if an individual received vaccine more than 5 years earlier and was younger than 65 years at the time of administration, revaccination should be given)
2. Persons aged 2 to 64 years with a chronic illness (congestive heart failure, cardiomyopathy, chronic pulmonary disease, diabetes, alcoholism, and liver disease)
3. Persons aged 2 to 64 years with functional or anatomic asplenia (when splenectomy is planned, PPSV23 should be given at least 2 weeks before surgery; a single revaccination is recommended at 5 years in subjects older than 10 years and at 3 years in subjects younger than 10 years)
4. Persons aged 19 to 64 years who smoke cigarettes or have asthma
5. Persons with cochlear implants

PPSV23 is recommended for immunocompromised persons 2 years and older with (a) HIV infection, (b) leukemia, (c) lymphoma, (d) Hodgkin disease, (e) multiple myeloma, (f) generalized malignancy, (g) chronic renal failure or nephrotic syndrome, (h) patients receiving immunosuppressive therapy including corticosteroids, and (i) organ and bone marrow transplant recipients.[24] A single revaccination should be given if 5 years or more have passed since the first dose in subjects older than 10 years. In subjects 10 years of age and younger, revaccination should be given 3 years after the previous dose.

PPSV23 induces type-specific antibodies (T-cell–independent mechanisms) with a twofold rise within 2 to 3 weeks in 80% of young healthy adults. No correlation of antibody levels and protection has been determined. Antibody levels to these strains remain elevated for at least 5 years. In certain individuals, these levels decline within 10 years. Children may be protected for only 3 to 5 years. Elderly individuals and patients with chronic disease, including immunosuppressing conditions may have lower antibody levels produced with the vaccine. Children younger than 2 years do not respond adequately to the vaccine.

PPSV23 vaccine efficacy has been debated in the literature. Study results generally point to a reduction in invasive pneumococcal disease in the general population and in the elderly. In immunosuppressed populations, the reduction in invasive disease is estimated at 50% to 80% with immunization.[23]

PPSV23 safety is well-documented. Local reactions occur frequently within the first 48 hours and generally are mild. Local erythema and induration (30%), local discomfort (40%), and local swelling (3%) are the side effects observed most commonly. Revaccination has been associated with self-limited injection-site reactions more commonly than after the first dose.

Pneumococcal Conjugate Vaccine

Invasive pneumococcal disease occurs even more frequently in children younger than 2 years than in those older than 65 years of age. The infection ranges from nasopharyngeal carriage to bacteremia and meningitis. Because of the lack of immune responsiveness in children younger than 2 years when exposed to polysaccharide vaccines, a conjugate vaccine was developed to protect young children from certain strains of *S. pneumoniae, but PCV13 also has a role in adult immunization.* Twelve of the 13 vaccine strains are included in PPSV23. In clinical use, the vaccine is associated with a dramatic decline in invasive disease not only in immunized young children but also in individuals in all age groups.[25]

Immunization of Children

PCV13 is administered as a 0.5-mL IM injection at 2, 4, and 6 months of age and between 12 and 15 months of age. A single dose of PCV13 should be administered to children aged 6 to 18 years with sickle cell disease or splenic dysfunction, HIV infection, immunocompromising conditions, cochlear implant, or cerebral spinal fluid leak.[25] PPSV23 can be used in conjunction with PCV13. PPSV23 should be administered after age 2 years and at least 2 months after the last dose of PCV13.

Immunization of Adults

The PCV13 offers additional protection over PPSV23 alone in adult high-risk populations. The ACIP recommended PCV13 for adults with immunocompromising conditions (Table 147-3).[23] PCV13 should be administered prior to PPSV23 in adults who have not been immunized previously. PCV13 should be administered with at least a year interval in those adults for whom it has been recommended and have already received one or more doses of PPSV23.

For adults aged 65 years and older who are not immunocompromised, shared clinical decision-making should be used for PCV13. Issues to consider include the low rate of invasive pneumococcal disease in this age group and that PCV13 is safe and effective. Clinicians may choose to routinely offer PCV13 to individuals age 65 years and older who live or travel to an area with low PCV13 coverage in young children, residents of long-term care facilities, or those with chronic conditions associated with higher risk of invasive pneumococcal disease, including heart, lung or liver disease, diabetes or alcoholism, and those who smoke cigarettes. All adults aged 65 years and older should routinely receive PCV13 if they are immunocompromised.[26]

TABLE 147-3

ACIP Recommendations for Use of PCV13 and PPSV23

Vaccine naive adults

- PCV13 first with PPSV23 administered at least 8 weeks later
- Second dose of PPSV23 at 5-year interval and PPSV23 at age 65 years and at least 5 years after the last dose

PPSV23-immunized adults

- PCV13 at least 1 year after the last dose of PPSV23
- Second dose of PPSV23 at 5-year interval and PPSV23 at age 65 years and at least 5 years after the last dose

Indications for PCV13 for adults 19 years and older

- Functional or anatomic asplenia
- Immunocompromising conditions
    - Congenital or acquired immunodeficiencies
    - HIV infection
    - Chronic renal failure or nephrotic syndrome
    - Leukemias, lymphomas, Hodgkin’s lymphoma
    - Generalized malignancy
    - Diseases requiring treatment with immunosuppressive drugs, including long-term systemic corticosteroids or radiation therapy
    - Solid organ transplantation
    - Multiple myeloma
- Cerebral spinal fluid leaks or cochlear implants

PCV13, 13-valent pneumococcal conjugate vaccine; PPSV23, 23-valent pneumococcal polysaccharide vaccine.

Data from Reference[23].

Poliovirus Vaccines

Poliomyelitis is a contagious viral infection that usually causes asymptomatic infection; however, in its serious form it causes acute flaccid paralysis. Poliovirus is spread via the fecal–oral route. The virus replicates in the upper respiratory tract, GI tract, and local lymphatics. The vast majority of polio infections are subclinical and asymptomatic. Polio has been eliminated from the United States since 1979, and the last case in Western Hemisphere was reported in 1991. Global eradication efforts are entering the final stages, and the eradication of polio should be accomplished in the next few years.

An inactivated vaccine developed by Jonas Salk was licensed for use in 1955. In 1987, an enhanced-potency inactivated polio vaccine (IPV) was introduced and that replaced the original inactivated vaccine. A live-attenuated oral polio vaccine (OPV) was developed by Albert Sabin in 1962. OPV was the primary immunizing agent for poliovirus infection. Widespread OPV use is responsible for the elimination of wild-type polio in most of the world. However, with no poliovirus circulation in the United States for years, IPV is the recommended vaccine for the primary series and booster dose for children.[27] OPV will continue to be used in areas of the world that have circulating poliovirus. The CDC maintains a stockpile of OPV to be used only in case of an outbreak.

The IPV series is administered routinely to children at ages 2, 4, and 6 to 18 months, and 4 to 6 years.[27] Primary polio immunization is recommended for all children up to age 18 years. Primary immunization of adults over age 18 years is not recommended routinely because a high level of immunity already exists in this age group, and the risk of exposure in developed countries is exceedingly small. However, unimmunized adults who are at increased risk for exposure because of travel, residence, or occupation should receive IPV series.

No serious side effects are attributable to IPV. Pregnant women should be given IPV only if there is a clear need, such as women who will be traveling or living in an area with endemic or epidemic poliovirus.

Rabies Vaccine and Immunoglobulin

Rabies is a virtually universally fatal infection in humans. Although all mammals are susceptible to rabies, carnivorous mammals are reservoirs of the virus and responsible for persistence of the virus in nature. In the United States, most human cases of rabies are from exposure to rabid bats, but raccoons, foxes, skunks, and coyotes are also associated with possible exposure. Worldwide, canines are the primary vectors. Transmission of rabies can occur via percutaneous, permucosal, or airborne exposure to the rabies virus. Circumstances favoring such transmission include animal bites and attacks and contamination of scratches, cuts, abrasions, and mucous membranes with saliva or other infectious material (brain tissue). Unprovoked attacks and daytime attacks by nocturnal animals are considered highly suspect. A few cases of person-to-person transmission have been reported.

Symptoms of rabies are nonspecific during the prodromal stage—fever, headache, malaise, irritability, nausea, and vomiting. The acute neurologic phase is characterized by hyperexcitability, hyperactivity, hallucinations, salivation, a fear of water, and air. Patients die within 5 days of presentation with these neurologic symptoms.

Human diploid cell vaccine, and purified chick embryo cell rabies vaccine are killed vaccines used for preexposure and postexposure rabies virus prophylaxis. Preexposure indications for rabies vaccine include persons whose vocation or avocation place them at high risk for rabies exposure, such as veterinarians, animal handlers, laboratory workers in rabies research or diagnostic laboratories, cavers, wildlife officers where animal rabies is common, and anyone who handles bats. Travelers who will be in a country or area of a country where there is a constant threat of rabies, whose stay is likely to extend beyond 1 month, and who may not have readily available medical services (eg, Peace Corps workers and missionaries) should be considered for preexposure prophylaxis. Rabies immunization of immunocompromised individuals should be postponed until the immunosuppression has resolved, or activities should be modified to minimize the potential exposure to rabies. If the vaccine is used in immunocompromised persons, antibody titers should be checked postimmunization. Pregnancy is not a contraindication if the risk of rabies is great. Both vaccine preparations can be administered for preexposure prophylaxis as a three-dose series of 1 mL IM on days 0 and 7 and once between days 21 and 28.[32] Individuals with ongoing risk of exposure—either continuous risk (eg, research laboratory staff or those involved in rabies biologics production) or individuals with frequent exposures (eg, those involved with rabies diagnosis, spelunkers, veterinarians, animal control workers, and wildlife workers in rabies-enzootic areas)—should undergo serologic testing every 6 months and 2 years, respectively, to monitor rabies antibody concentrations. A booster dose is recommended if the complete virus neutralization is less than 1:5 serum dilution by the rapid fluorescent focus inhibition test.[28]

Preexposure prophylaxis does not eliminate the need for postexposure therapy. Persons previously immunized with rabies vaccine or those who previously received postexposure prophylaxis should receive two 1-mL IM doses of rabies vaccine on postexposure days 0 and 3.[32] Rabies Ig should not be given to this group.

Postexposure prophylaxis should be given after percutaneous or permucosal exposure to saliva or other infectious material from a high-risk source. Each case must be considered individually. Consideration needs to be given to the geographic area, species of animal, circumstances of the incident, and type of exposure. Local or state health departments should be contacted for assistance. Thorough cleansing of the wound with soap and water followed by irrigation with a virucidal agent such as povidone–iodine solution is an extremely important part of the management of rabies-prone wounds. Individuals who have not been immunized previously should receive the recommended regimen of rabies Ig (see Rabies Immunoglobulin below) and four doses of rabies vaccine 1 mL IM on days 0, 3, 7, and 14 after exposure. However, a fifth dose in a series should be considered if the exposed individual is immunocompromised. Vaccine response for these immunocompromised individuals should be checked.[28] Rabies vaccine must be administered in the deltoid muscle in adults and in the anterolateral thigh in children. The gluteal region should not be used.[1,28]

Adverse reactions to rabies biologicals are less common and less serious with the currently available vaccines compared with previously used preparations. Local or mild systemic symptoms can typically be managed with anti-inflammatory medications or antihistamines. Systemic allergic reactions ranging from hives to anaphylaxis occur in a small number of subjects. Given the lack of alternative therapy and the fact that rabies infection is almost always fatal, persons exposed to rabies who do have adverse reactions should continue the vaccine series in a setting with medical support services.[28]

Human rabies Ig is used in conjunction with rabies vaccine as part of postexposure rabies management for previously unvaccinated individuals. The product is derived from plasma obtained from donors who have been hyperimmunized with rabies vaccine and have high titers of circulating antibody.

In persons who previously have not been immunized against rabies, rabies Ig is given simultaneously with rabies vaccine to provide optimal coverage in the interval before immune response to the vaccine occurs. The efficacy of this regimen has been clearly demonstrated as it provides virtually complete protection from rabies when administered with the vaccine series promptly following exposure.[28] Rabies Ig does not interfere with vaccine-induced antibody formation. Its use is not recommended beyond 8 days after initiation of the vaccine series nor in persons previously immunized to rabies.

Human rabies Ig is administered in a dose of 20 international units/kg (0.133 mL/kg). If anatomically feasible, the entire dose should be infiltrated around the wound(s). Any remaining volume should be administered IM at a site distant from the rabies vaccination site. This product should never be administered by the IV route. Because other antibodies in the rabies Ig may interfere with the response to live-virus vaccines (MMR and varicella), it is recommended that these immunizations be delayed for 3 months.[1]

Side effects are rare but may include local soreness at the wound or IM injection site and mild temperature elevations. Pregnancy is not a contraindication to its use.

Rotavirus Vaccine

Rotavirus infection is virtually universal by age 5 years. Rotavirus can cause severe dehydrating diarrhea primarily among children aged 4 months to 23 months. The virus is usually transmitted fecal-orally and has a seasonal pattern with infection most likely in winter. In the pre-vaccine era, about 50% of hospitalizations for diarrhea among children were attributed to rotavirus.

Two vaccines for infants are available in the United States. A pentavalent human-bovine reassortment vaccine is administered orally at ages 2, 4, and 6 months. The monovalent human rotavirus vaccine is administered orally at ages 2 and 4 months. If brands of vaccines are changed during the series, a three-dose series should be used. The infant should be younger than 15 weeks of age for dose 1, and the maximum age for the last dose of the vaccine is 8 months.[7]

Rotavirus vaccination confers a small increased risk of intussusception following vaccine administration. Intussusception is a condition in which the bowel folds in itself in a telescoping fashion which can lead to inflammation, ischemia, or bowel obstruction. A history of intussusception is a contraindication to rotavirus vaccine. Severe combined immunodeficiency is also a contraindication.[29]

Rubella Vaccine

Rubella (German measles) is characterized by an erythematous rash, lymphadenopathy, arthralgia, and low-grade fever. The most important consequence of rubella infection occurs during pregnancy, particularly during the first trimester. Congenital rubella syndrome is associated with auditory, ophthalmic, cardiac, and neurologic defects. Rubella infection during pregnancy can also result in miscarriage or stillbirth. The primary goal of rubella immunization is to prevent congenital rubella syndrome. Rubella is no longer endemic in the United States, but high immunization rates are necessary to prevent rubella outbreaks from imported cases.[9]

Rubella vaccine contains live-attenuated rubella virus. The vaccine is available in combinations with measles and mumps (as MMR), or varicella (MMRV) vaccines.

Rubella vaccine induces antibodies that are protective against wild-virus infection. A second dose is recommended, at the same time measles vaccine is administered (as a second dose of MMR). The vaccine is indicated for children older than 1 year of age. Individuals born before 1957 are assumed to be immune to rubella except for females who could become pregnant. Therefore, all females of childbearing potential should have documentation of receiving at least one dose of a rubella-containing vaccine or laboratory evidence of immunity. The vaccine should not be given to immunosuppressed individuals, although MMR vaccine should be administered to individuals with HIV infection without evidence of immunity (see section "Measles Vaccine").[9] Adverse effects of the rubella virus vaccine tend to increase with the age of the recipient. Mild symptoms are similar to wild-virus infection and include lymphadenopathy, rash, urticaria, fever, malaise, sore throat, headache, myalgias, and paresthesias of the extremities. These symptoms occur 7 to 12 days after vaccination and last 1 to 5 days. Joint symptoms occur more often in susceptible postpubertal females. Arthralgia occurs in 25% of vaccinees, and 10% have arthritis-like symptoms. These symptoms usually begin 1 to 3 weeks after vaccination, persist for 1 day to 3 weeks, and rarely recur.[9]

The rubella vaccine has never been associated with congenital rubella syndrome, but its use during pregnancy is contraindicated. However, routine pregnancy testing prior to vaccination is not recommended. Females should be counseled not to become pregnant for 4 weeks following vaccination.[9]

Tetanus Toxoid Adsorbed and Tetanus Immunoglobulin

Tetanus is a severe acute illness caused by the exotoxin of *Clostridium tetani*. Tetanus is the only vaccine-preventable disease that is not contagious as it is acquired from the environment. Tetanus toxin interferes with neurotransmitters that promote muscle relaxation, leading to continuous muscle spasms that are characteristic of tetanus. Death can be due to the tetanus toxin itself or secondary to a complication such as aspiration pneumonia, dysregulation of the autonomic nervous system, or pulmonary embolism.

Tetanus toxoid is an adjuvanted suspension of the toxoid derived from *C. tetani*. A series of three 0.5-mL doses of tetanus toxoid elicits protection in virtually all individuals. Primary vaccination provides protection for at least 10 years.[8] Additional doses of tetanus toxoid (combined with diphtheria toxoid, ie, Td) are recommended as part of wound management if a patient has not received a dose of tetanus toxoid within the preceding 5 years. For minor or clean wounds, no dose is given (Table 147-4). Tetanus Ig should be given to individuals who have received fewer than three doses of tetanus toxoid and have more serious wounds. It can be administered with tetanus toxoid, provided that separate syringes and separate injection sites are used.

TABLE 147-4

Tetanus Prophylaxis

Vaccination History	Clean, Minor Wounds		All Other Wounds	
	Td[a]	TIG	Td or Tdap[a]	TIG
Unknown or fewer than three doses	Yes	No	Yes	Yes
Three or more doses	No[a,b]	No	No[a,c]	No

[a] A single dose of Tdap should be used for the next dose of tetanus–diphtheria toxoid for individuals aged >10 years.

[b] Yes, if more than 10 years since the last dose.

[c] Yes, if more than 5 years since the last dose.

Data from Reference[8].

In children, primary immunization against tetanus usually is offered in conjunction with diphtheria and pertussis vaccination (using DTaP or a combination vaccine that includes other antigens used to decrease the number of injections to complete the childhood immunization schedule) at age 2, 4, 6, and 15 to 18 months.[8] In children 7 years and older and in adults who have not been immunized previously, a series of three 0.5-mL doses of a tetanus toxoid-containing vaccine is administered IM initially. The first two doses are given 1 to 2 months apart, and the third dose is recommended at 6 to 12 months after the second dose. Boosters are recommended every 10 years, and unless there is contraindication to diphtheria toxoid, Td or Tdap should be used.[8]

Adverse reactions to tetanus toxoid include mild-to-moderate local reactions at the injection site, such as warmth, erythema, and induration. Occasionally, a nodule at the injection site develops and remains for a few weeks. This type of reaction is indicative of high preexisting antibody concentrations, and additional doses of toxoid should not be given any sooner than 10 years. Local reactions do not limit the use of the toxoid for further dosing.

Tetanus Ig is a sterile, concentrated, nonpyrogenic solution of Igs prepared from hyperimmunized humans. It is used to provide passive immunity to tetanus after the occurrence of traumatic wounds in nonimmunized or suboptimally immunized persons (see Table 147-4).[8] A dose of 250 to 500 units IM should be administered. When administered with tetanus toxoid, separate sites for administration should be used. Tetanus Ig also is used for treatment of tetanus. In this setting, a single dose of 3,000 to 6,000 units IM is administered.

Adverse effects of tetanus Ig include pain, tenderness, erythema, and muscle stiffness at the injection site, which may persist for several hours. Systemic reactions occur rarely. IV administration has been associated with severe adverse reactions and is not recommended.

Varicella and Zoster Vaccines

Varicella is a highly contagious disease caused by varicella-zoster virus. The clinical illness is characterized by the appearance of successive waves of pruritic vesicles that rapidly crust over. Malaise and fever are common and last for 2 to 3 days. The virus remains dormant in the dorsal ganglia and reactivates as herpes zoster, also known as *shingles.* Although the exact stimulus for reactivation is unknown, a decrease in varicella-specific cell-mediated immunity associated with age or immunosuppression appears to be necessary but not sufficient for reactivation.

Varicella Vaccine

Live-attenuated varicella vaccine contains the Oka/Merck strain of varicella virus. Varicella vaccine must be kept frozen and protected from light. Once reconstituted, it must be administered subcutaneously within 30 minutes.[30] The varicella vaccine is recommended for all children at 12 to 15 months of age, with a second dose prior to entering school between ages 4 and 6 years.[30] Two doses separated by 4 to 8 weeks should be administered to anyone who lacks immunity to varicella. Because the varicella vaccine is a live vaccine, it is contraindicated during pregnancy and in immunocompromised individuals. An exception is children with asymptomatic or mildly symptomatic HIV infection, who should receive two doses of varicella vaccine 3 months apart. In addition, children with humoral immune deficiencies may be immunized. Persons who have received blood, plasma, or Ig products in the recent past should not receive varicella vaccine because of concern that passively acquired antibody will interfere with response to the vaccine. The recommended time interval between antibody-containing products and varicella vaccine depends on the dose of Ig (see Table 147-2).[1] Although no adverse events associated with salicylate use after vaccination have been reported, salicylates should be avoided for 6 weeks after vaccination because of the association of salicylate use and Reye syndrome following varicella infection.[36]

Common adverse events include local swelling, and erythema at the injection site occur in up to 32% of patients and fever in 10% to 15%. A varicella-like rash occurs in approximately 4% of vaccinees, accompanied by few, if any, systemic symptoms. The rash may be localized at the injection site or generalized. Lesions usually are few in number (2-10) and often papular rather than vesicular. Transmission of vaccine virus to susceptible close contacts has occurred but is rare and believed to occur only when the vaccinee develops a rash. Because the risk of vaccine virus transmission is low and primary infection can be severe, vaccination of household contacts of immunocompromised patients is recommended to prevent introduction of varicella into the household.[30]Varicella vaccine is contraindicated in immunosuppressed individuals and those who are pregnant. Aspirin should be avoided for 6 weeks following varicella vaccine administration because of its association with Reye syndrome. Also, a caution in those with a personal or family history of seizures exists for the use of MMRV. Consider using the MMR and varicella vaccines separately.[30]

Zoster Vaccine

After the primary infection with varicella-zoster virus manifested as chicken pox, the virus remains latent in the dorsal ganglia. Herpes zoster, also called *shingles*, occurs upon reactivation of varicella-zoster virus associated with waning cellular immunity to the virus. Herpes zoster can occur at any age, but the incidence dramatically increases with age. The rate of disease increases sharply after age 50 years. The disease rate in individuals older than 80 years of age is 15 cases per 1,000 person-years. Patients with HIV, cancer, or other conditions associated with immunosuppression are at increased risk for disease.[31]

The clinical presentation of herpes zoster usually is a vesicular eruption limited to one dermatome. The most common complication is postherpetic neuralgia, which is pain that persists for weeks to years after the skin lesions have healed. The risk of postherpetic neuralgia increases with age. Virtually no risk of developing postherpetic neuralgia with herpes zoster exists prior to age 50 years, but the risk increases to 50% to 75% after ages 60 and 75 years, respectively.[32]

A recombinant zoster vaccine (RZV) with an adjuvant is recommended by the ACIP for use in immunocompetent individuals aged 50 years and older as a two-dose series at 0 and 2 to 6 months.[31] The vaccine is approximately 91% effective for the prevention of zoster.[41] Although the incidence of serious adverse effects were similar in the vaccine and placebo groups, the incidence of injection site and systemic adverse events were much higher in the vaccine group. Almost 80% of those who receive RZV report injection site pain with 9% of those reporting injection site reactions that interfere with their normal activities. No difference in the incidence of injection site reactions were found when comparing dose 1 to dose 2.[31]

Varicella-Zoster Immunoglobulin

Varicella-zoster Ig is used after exposure to varicella for passive immunization of susceptible immunodeficient patients or other susceptible individuals at particularly high risk for complications of varicella infection. Postexposure prophylaxis with varicella-zoster Ig is indicated for the following susceptible individuals: (a) immunocompromised patients without evidence of immunity, (b) neonates whose mothers develop varicella within 5 days before or 2 days after delivery, (c) hospitalized premature infants (more than 28 weeks of gestation) whose mothers have no evidence of immunity, (d) hospitalized preterm infants (less than 28 weeks' gestation or weight less than 1,000 g), and (e) susceptible pregnant individuals.[30] If varicella is prevented, vaccination should be offered at a later date. Exposure to varicella is defined as direct indoor contact for more than 1 hour with an infectious person. A negative history of clinical disease is not a reliable indicator of varicella susceptibility. Most people with a negative clinical history will have detectable antibody on laboratory testing.

For maximum effectiveness, varicella-zoster Ig must be given as soon as possible and not more than 10 days following exposure.[30] Because this agent may only attenuate infection, patients who receive varicella-zoster Ig still may have a period of communicability, and varicella-zoster Ig may prolong the incubation period to 28 days. Antiviral therapy can be initiated if signs and symptoms of varicella infection become apparent.

Administration of varicella-zoster Ig is by the IM route at doses of 125 plaque-forming units per 10 kg of body weight up to 625 units (five vials) for patients weighing more than 40 kg. The dose for newborn infants is 125 units.[30]

OTHER IMMUNOBIOLOGICS

Immunoglobulin

Ig is available as both intramuscular immunoglobulin (IMIG) and IV immunoglobulin (IVIG) preparations. These products contain a wide spectrum of IgG antibodies to the pathogens prevalent in the area from which the donors were obtained. IMIG typically contains 15% to 18% protein and not less than 90% IgG. A number of IVIG preparations are available commercially in the United States. Generally, these preparations contain greater than 90% IgG monomers and trace to small amounts of IgA. Because different processes are used in the preparation of IMIG and IVIG products, they are not interchangeable.

When administered either IV or IM, Ig distributes in approximately 5% of the body weight of the recipient. The plasma half-life of Ig ranges from 18 to 32 days. This range of half-life probably is attributable to the variation in the half-life of IgG subclasses. Peak serum concentrations occur immediately with IVIG but within 2 days with IMIG. After the initial period of equilibration, circulating IgG levels are superimposable between IV and IM equivalent dosages. No dosage adjustment is necessary in patients with renal insufficiency, hepatic insufficiency, or both, dialysis patients, or geriatric patients.

⑥ Ig is indicated in a wide variety of circumstances to provide passive immunity to individuals. The indications for IMIG differ from those for IVIG. IMIG is indicated for providing passive immunity in patients with hepatitis A infections in those for whom IMIG is recommended in addition to immunization, hepatitis B exposures (however, hepatitis B Ig is significantly more effective), measles, varicella, and primary immunodeficiency diseases. Although IMIG is indicated for the treatment of primary immunodeficiency, IVIG is better tolerated and is more effective. IMIG is not indicated for prevention of rubella, mumps, or poliomyelitis. **Table 147-5** lists the suggested dosages of IMIG for prevention or attenuation of various infectious diseases.

TABLE 147-5

Indications and Dosage of Intramuscular Immunoglobulin in Infectious Diseases

Primary immunodeficiency states	1.2 mL/kg IM then 0.6 mL/kg every 2-4 weeks
Hepatitis A exposure	0.02 mL/kg IM within 2 weeks if <1 year or >39 years of age
Hepatitis A prophylaxis	0.02 mL/kg IM for exposure <3 months’ duration
	0.06 mL/kg IM for exposure up to 5 months’ duration
Hepatitis B exposure	0.06 mL/kg (HBIG preferred in known exposures)
Measles exposure	0.5 mL/kg (maximum dose 15 mL) as soon as possible

There are many licensed indications, as well as off-label uses, for IVIG.[43] The therapeutic dose of IVIG is set empirically at 2 g/kg, often given as five daily doses of 400 mg/kg each. Mechanisms of IVIG action for treatment of these conditions have been hypothesized.

1. *Primary Immunodeficiency States.*[33,34] In primary immunodeficiency states, monthly doses of between 100 and 800 mg/kg are administered; the average dose is 200 to 400 mg/kg. The immunodeficiency states for which IVIG is indicated include both antibody deficiencies and combined immune deficiencies. Significant reactions can occur in patients with low intrinsic levels of IgA given IVIG with greater amounts of IgA. An IVIG product with low amounts of IgA should be used for these patients.

2. *Immune Thrombocytopenia.*[35] For the treatment of hemorrhage associated with immune thrombocytopenia (ITP), doses of 1 g/kg daily for 2 to 3 days plus high-dose methylprednisolone are indicated. Adults tend to respond less well to IVIG than do children. IVIG is acceptable for treatment of both chronic and acute ITP, and IVIG has been used for ITP associated with pregnancy without adverse effects on the fetus. Corticosteroids remain the drugs of choice for adult ITP. In thrombotic thrombocytopenia purpura, IVIG is reported to be effective in patients who do not respond to plasmapheresis. Other platelet disorders in which IVIG may be useful include neonatal immune thrombocytopenia, perinatal autoimmune thrombocytopenia, drug-induced thrombocytopenia, thrombocytopenia secondary to infection, and transfusion-refractory thrombocytopenia; however, the data supporting these uses are minimal.

3. *Chronic Lymphocytic Leukemia.*[36] IVIG is used as a prophylactic measure in patients with chronic lympocytic leukemia who have had a serious bacterial infection.

4. *Kawasaki Disease.*[37] This disease, which generally occurs in children, carries the hallmark of development of coronary artery abnormalities. Generally, the American Academy of Pediatrics recommends that if the strict criteria for Kawasaki disease are met, an IVIG dose of 400 mg/kg/day for four consecutive days be used or, preferably, 2 g/kg as a single dose. The dose should be administered within 10 days of disease onset. Aspirin therapy also should be initiated.

5. *Pediatric HIV infection.*[38] IVIG prevents serious bacterial infections in children with HIV infection. However, in the era of highly active anti-retroviral therapy, its use has waned.

6. *Allogeneic bone marrow transplantation.*[39]

7. *Chronic inflammatory demyelinating polyneuropathy.*[39] This disabling neuropathy often responds to corticosteroids, IVIG, or plasmapheresis.
8. *Multifocal motor neuropathy*[40] IVIG is considered first-line therapy.
9. *Kidney transplantation involving a recipient with high antibody concentrations or an ABO-incompatible donor.*[41] Some transplant recipients have antibody concentrations that present an immunological barrier to transplantation. Desensitization can be accomplished using IVIG.

Many other uses of IVIG have been identified. These uses are off-label but may be generally accepted in the medical community for routine treatment.[33]

7 Adverse effects of Ig vary with the route of administration. Following IMIG, pain, tenderness, and muscle stiffness persisting for hours or days are common. Repeat courses may cause sensitization with resulting allergic reactions. Chills, fever, nausea, and vomiting often are related to the rate of the infusion.[42] Infusion should be given at a rate of 0.01 to 0.02 mL/kg/min for 30 minutes. If no reactions occur, then the rate can be increased to 0.02 to 0.04 mL/kg/min. If reactions do occur, the infusion should be stopped for 30 minutes and restarted at a lower rate. Although recommendations for infusion rate vary slightly depending on the preparation, the guidelines presented can be followed for the various IV preparations.

Most adverse reactions are mild and transient. Arthralgia, myalgia, fever, pruritus, nausea, vomiting, chest tightness, palpitations, diaphoresis, dizziness, pallor, and respiratory distress have been reported. Rarely, aseptic meningitis has occurred from a few hours to 2 days after high-dose infusion. The syndrome resolves within days without sequelae. Acute renal failure has been reported, primarily in individuals with underlying renal dysfunction, diabetes, sepsis, volume depletion, or other nephrotoxic drugs or in patients older than 65 years. To minimize the risk, ensure adequate hydration prior to infusion and choose an IVIG product that does not contain high-sucrose concentrations for individuals at high risk.[42]

Ig products are derived from human blood. Precautions such as donor screening and fractionation procedures and solvent–detergent treatment during the manufacturing process render the IVIG products free of HIV and hepatitis B and C viruses. Although no manufacturing process can guarantee no viral contamination, the potential infection risk from Ig preparations is very small.

Rh_o(D) Immunoglobulin

8 Second only to the ABO blood group system, Rhesus antigen D [Rh_o(D)] is an important antigen in human blood. The Rh_o(D) locus encodes this antigen, but this locus is absent in approximately 15% of the population. Individuals lacking the Rh_o(D) locus are Rh_o(D) negative and have the potential to mount an antibody response to erythrocytes with the Rh_o(D) present. Rh_o(D) incompatibility during pregnancy can lead to sensitization of the mother. The maternal antibodies developed following normal fetal leakage of erythrocytes to the mother can cause hemolytic disease of the newborn during subsequent pregnancies.

Rh_o(D) Ig is a sterile solution of Igs prepared from human sera with high titers of Rh_o(D) antibody. Rh_o(D) Ig suppresses the antibody response and formation of anti-Rh_o(D) in Rh_o(D)-negative individuals exposed to Rh_o(D)-positive blood. Administration of Rh_o(D) Ig prevents hemolytic disease of the newborn in subsequent pregnancies with a Rh_o(D)-positive fetus. When administered within 72 hours of delivery of a full-term infant, Rh_o(D) Ig reduces active antibody formation from 1% to about 0.2%. The reduction in antibody formation is lower when Rh_o(D) Ig is given beyond 72 hours postpartum. Smaller doses of Rh_o(D) Ig are used after abortion, miscarriage, amniocentesis, or abdominal trauma. In addition, Rh_o(D) Ig is used in the case of a premenopausal female who is Rh_o(D) negative and has inadvertently received Rh_o(D)-positive blood or blood products.[43]

The dosage of Rh_o(D) Ig varies with the indication. A standard dose of 300 mcg is given within 72 hours of a term delivery. Occasionally, when the fetus is known to be Rh_o(D) positive, a 300-mcg dose is given at 28 weeks' gestation and within 72 hours after delivery. For postpregnancy termination occurring up to 13 weeks' gestation, one microdose (50 mcg) vial is given within 72 hours. For pregnancy termination after 13 weeks, one standard dose (300 mcg) is given within 72 hours. In other circumstances, such as in abdominal trauma, amniocentesis, or transfusion accidents, the dosage (number of standard dose vials) is based on the estimated packed red blood cell volume of fetal/maternal hemorrhage divided by 15. Rh_o(D) Ig is administered IM only.

Adverse reactions to $Rh_o(D)$ Ig include injection-site tenderness and fever. $Rh_o(D)$ may minimally interfere with response to rubella or varicella vaccine. Rubella- or varicella-seronegative females should be immunized with MMR or MMRV at hospital discharge even if they received $Rh_o(D)$ Ig postpartum.[1]

Vaccine Hesitancy

Vaccine confidence is the trust that individuals and providers have in recommended vaccines, in those who administer vaccines, and the policies and processes by which vaccines are developed, manufactured, licensed, and recommended.[44] Vaccine hesitancy is a global threat to protection conferred by strong immunization programs. A variety of justifications for choosing not to vaccinate exist. The Strategic Advisory Group of Experts (SAGE), a working group under the World Health Organization (WHO), defined three overarching drivers for vaccine hesitancy: complacency, convenience, and confidence.[45] This "3 Cs Model" defined complacency as a low perceived risk of contracting vaccine-preventable diseases, and therefore low necessity to receive vaccines. Convenience is based on socioeconomic factors such as availability, accessibility, affordability, and ability to understand, such as language barriers or low health literacy. Confidence stems from trust in various aspects of healthcare, such as the vaccine itself, healthcare professionals administering vaccines, or policy-makers who advocate for vaccination and determine their need.

Communication is key to relaying a vaccine message starting with empathy and understanding. Healthcare providers should assume that individuals want to be vaccinated and make a strong recommendation for vaccines. Healthcare workers must be prepared to share facts that address misinformation and respond to patient questions. An active discussion of expected side effects is associated with patient confidence. Finally, the conversation can be concluded by encouraging the individual to take action to get the vaccine.[46]

VACCINE INFORMATION RESOURCES

The field of vaccinology is developing rapidly, with numerous changes in recommendations for vaccine use made each year. Keeping up to date with the current recommendations can be a challenge. The childhood and adult immunization schedules are updated frequently and published annually. Recommendations for the use of influenza vaccine are issued annually. Healthcare providers involved in primary care and immunization delivery must keep themselves abreast of these changes in a systematic way. Reading electronic newsletters and browsing reliable websites are efficient methods for obtaining information (Table 147-6). Although several excellent, reliable, and timely websites exist, hundreds of sites with misleading and incorrect information also exist. Many of these sites are targeted at parents.

Parents and patients often have questions regarding vaccine safety. The Vaccine Education Center at the Children's Hospital of Philadelphia has several documents that may answer those questions (http://www.chop.edu/centers-programs/vaccine-education-center). The CDC is another source of information for parents (https://www.cdc.gov/vaccines/parents/vaccine-decision/index.html). Vaccines are the only class of medications to which nearly every patient is exposed. Knowledge of these agents is critical to providing pharmaceutical care. Dramatic progress in public health has been made through the appropriate use of immunization. Additional improvements in quality of life and mortality can be made through continued increases in vaccination coverage with careful attention to this aspect of care by all healthcare providers.

ABBREVIATIONS

ACIP	Advisory Committee on Immunization Practices
CDC	Centers for Disease Control and Prevention
DTaP	diphtheria, tetanus toxoids, and acellular pertussis
Hib	*Haemophilus influenzae* type b
HPV	human papillomavirus
Ig	Immunoglobulin
IMIG	intramuscular immunoglobulin
IPV	inactivated polio vaccine
ITP	idiopathic (immune) thrombocytopenic purpura
IVIG	IV immunoglobulin
MenB	Meningococcal serogroup B
MMR	measles, mumps, rubella vaccine
MMRV	measles, mumps, rubella, varicella vaccine
MSM	men who have sex with men
OPV	oral polio vaccine

SELF-ASSESSMENT QUESTIONS

1. Which of the following is an example of a situation in which vaccine-induced immune response would be poor?

   A. Meningococcal conjugate vaccine administered to a healthy 12-year-old child.

   B. Hepatitis B vaccine administered with a 1.5-in. (3.8 cm) needle to a 22-year-old woman who weighs 125 kg.

   C. Third dose in the inactivated polio vaccine series administered to a 12-month-old child.

   D. Measles, mumps, rubella vaccine administered to a 4-month-old infant.

2. Which of the following is the most likely adverse effect of IVIG use in a patient with immune thrombocytopenia purpura and congestive heart failure?

   A. Anaphylaxis associated with native IgM antibodies

   B. Kawasaki disease

   C. Volume overload

   D. Chronic renal failure

3. Michael is a 5-year-old boy who presents for his well-child visit prior to entering kindergarten. His past medical history is unremarkable except for an anaphylactic reaction to amoxicillin 4 days ago when he was being treated for a tooth abscess. He was seen in the emergency room and given prednisone 40 mg daily for 5 days and azithromycin for 5 days. Although he was up-to-date on his childhood immunization at age 36 months, he now presents for routine immunizations prior to entering school. Which of the following strategies is recommended to accomplish administration of all needed vaccines as soon as possible?

   A. Administer DTaP, MMRV, IPV today

   B. Administer DTaP, IPV today, and postpone MMRV until he has been off prednisone for 3 months

   C. Administer no immunizations until he has been off prednisone for 3 months

   D. Administer DTaP and IPV today and postpone MMRV until he has been off antibiotics for 2 weeks

4. Which of the following describes the rationale for Rh_o(D) antibody treatment?

   A. Administered to an Rh-negative infant to prevent it from developing antibodies to its red blood cells

   B. Administered to an Rh-positive mother to prevent her from developing antibodies to her Rh-negative infant

   C. Administered to an Rh-negative mother to prevent her from developing antibodies that may cause her to become anemic

   D. Administered to an Rh-negative mother to prevent her from developing antibodies to Rh-positive red blood cells that may cause anemia in the fetus in future pregnancies

5. Which of the following infections is pooled human immunoglobulin useful in preventing?

   A. Measles

   B. Diphtheria

   C. Yellow fever

   D. Guillain-Barré syndrome

6. A vaccine for a hypothetical viral infection that is particularly problematic in young infants has been developed. The vaccine is a whole virus inactivated preparation that is administered by the intramuscular route. Which of the following is likely true about its use?

   A. Children younger than 2 years of age will not likely mount an immune response to it.

   B. Its administration should be separated from the administration of hepatitis B immunoglobulin by 4 months.

   C. Multiple doses will be required to induce a protective immune response

   D. A single dose will induce long-term protection

7. Justin is a 22-year-old male who had significant contact with a raccoon deemed to have rabies. The patient received rabies immunoglobulin and began the inactivated rabies vaccine series (doses on days 0, 3, 7, 14, and 28) in the emergency room yesterday. He now presents for follow-up with employee health service. Upon review of his health record including his immunization record, a second dose of a measles-containing vaccine is recommended because he is a healthcare worker. Which of the following strategies is recommended for the second dose of MMR vaccine?

   A. Administer an MMR vaccine now

   B. Administer the MMR vaccine in 4 weeks

   C. Administer an MMR vaccine in 4 months

   D. Administer an MMR vaccine in 6 months

   Use this case for the next two questions.

   Sarah is a 24-year-old elementary school teacher who is 14 weeks pregnant. This is her first pregnancy. She was noted to be rubella seronegative on routine prenatal screening laboratory panel. She was age-appropriately immunized as a child.

8. Which of the following recommendations is appropriate for the administration of a dose of rubella-containing vaccine?

   A. Vaccinate postpartum at hospital discharge.

   B. Vaccinate now to prevent possible congenital rubella syndrome.

   C. Vaccinate 3 months postpartum.

   D. No rubella vaccine should be given as she received the MMR as a child.

9. Which of the following vaccines are recommended for Sarah during her pregnancy?

   A. Tdap and inactivated influenza vaccines.

   B. Rubella and live-attenuated influenza vaccines.

   C. Td and inactivated influenza vaccines.

   D. No vaccines should be administered during pregnancy.

10. Mr. Olden is a 46-year-old man who has just been diagnosed with type 2 diabetes. He has not received any immunizations as an adult that he can remember and has not seen a physician since his military physical. Which of the following vaccines are recommended?

   A. Hepatitis A series, hepatitis B series, PPSV23, annual inactivated influenza, Tdap

   B. PPSV23, annual inactivated influenza, Tdap, hepatitis B series

   C. Hepatitis A series, hepatitis B series

   D. PCV13, annual influenza, Tdap

11. For which of the following individuals would you recommend PPSV23 revaccination?

   A. A 72-year-old man with COPD who was vaccinated 5 years ago

   B. A 66-year-old woman with diabetes who was vaccinated when she was 62

   C. A 44-year-old man with HIV who was vaccinated at the time of HIV diagnosis 5 years ago

   D. A 62-year-old kidney transplant patient who was vaccinated prior to her transplant 3 years ago

12. What action is recommended if the interval between doses of human papillomavirus vaccine is longer than the recommended interval?

    A. Add one additional dose

    B. Restart the series from the beginning

    C. Continue the series, ignoring the prolonged interval

    D. Perform a serologic test to determine if a vaccine response has been mounted

13. Mr. North is a 48-year-old male who is being seen for a pre-anesthesia physical prior to a planned uncomplicated hernia repair scheduled in two weeks. He smokes a pack of cigarettes daily. He is otherwise healthy, on no medications, and has not been immunized as an adult. Which of the following vaccines are recommended?

    A. MMR, Td, annual live-attenuated influenza

    B. Td, annual live-attenuated influenza, *Haemophilus influenza* type b, meningococcal, PCV 13 followed by PPSV23 in 8 weeks

    C. Tdap, annual inactivated influenza, PPSV23, zoster

    D. Tdap, annual inactivated influenza, PPSV23

14. Which of the following describes the procedure for administering an intramuscular immunization to an adult?

    A. Insert the needle at a 45° angle

    B. Use a 21- to 23-gauge needle in a length of 5/8 in. (1.6 cm)

    C. Use a 25-gauge needle in a length of 1 to 1.5 in. (2.5-3.8 cm)

    D. Use the deltoid muscle or the gluteus maximus for the injection site

15. Which of the following describes an advantage of the VAERS?

    A. All vaccine adverse events that occur in the United States are reported.

    B. Only common adverse events are collected.

    C. Adverse event rates can be calculated.

    D. Risk factors for adverse events can be evaluated.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D.** Young children must be at least 12 months old before the measles, mumps, rubella vaccine is administered as maternal antibody can neutralize the live vaccine viruses before the child has a chance to mount an immune response to the vaccine. Meningococcal conjugate vaccine is indicated for a 12-year-old child, and the third dose of inactivated polio vaccine is recommended for a 12-month-old child. An appropriately long needle is being used for administration of a dose of hepatitis B vaccine to an obese 22-year-old female.

2. **C.** The dose of IVIG for treatment of immune thrombocytopenia purpura is 1 g/kg daily for 2 or 3 days. The volume associated with those infusions is large and may result in volume overload, particularly in an individual at risk, such as someone with congestive heart failure.

3. **A.** This child can be vaccinated without regard to his current antibiotic therapy or short prednisone burst. He can receive DTaP, MMRV, and IPV today as recommended for a child aged 4 to 6 years.

4. **D.** The Rh-negative mother may mount an immune response to her Rh-positive fetus. Rho(D) antibody is administered to the mother to prevent her

from developing antibodies to Rh-positive red blood cells that may cause anemia in the fetus during future pregnancies.

5. **A.** Pooled human immunoglobulin can be used for postexposure prophylaxis of measles. It is not useful for the prevention of diphtheria or yellow fever. IVIG is used as a treatment option for Guillain-Barré syndrome.
6. **C.** Because the hypothetical vaccine is an inactivated vaccine, multiple doses will likely be needed to induce immunity in young infants. Immunoglobulin administration and long-term protection are typically properties of live-attenuated vaccines.
7. **C.** MMR is a live vaccine so its administration must be separated from immunoglobulin containing products. Using Table 147-2, the recommended interval between RIG and MMR vaccine is 4 months.
8. **A.** Live vaccines (MMR) are not recommended for administration to pregnant females so the vaccine should be administered at the completion of the pregnancy—postpartum at hospital discharge.
9. **C.** Tdap should be administered late in the second or during the third trimester to females during each pregnancy. Pregnant females are at particularly high risk for hospitalization or death from influenza infection so seasonal inactivated influenza vaccine is recommended.
10. **B.** This individual needs adult vaccines (Tdap, annual inactivated influenza vaccine) and other vaccines indicated because he has type 2 diabetes (PPSV23 and hepatitis B series).
11. **C.** PPSV23 is repeated after a 5-year interval for individuals who are at particularly high risk for invasive pneumococcal disease, such as the individual with HIV infection. A single dose is administered after age 65 years.
12. **C.** As for most vaccine series, the prolonged interval can be ignored and the series completed with the recommended number of doses.
13. **D.** This individual needs adult vaccines (Tdap, annual inactivated influenza vaccine) and vaccines indicated because he is a smoker (PPSV23).
14. **C.** Intramuscular vaccines are administered using a 23- to 25-gauge needle that is inserted at a 90° angle to the skin into the deltoid.
15. **D.** The VAERS is a passive system that allows healthcare providers and patients to report adverse events following immunization. The system allows risk factors for adverse events to be considered, but adverse event rates cannot be determined as the number of vaccines administered (the denominator) is not known. Also, consider that not all adverse events are reported.

Chapter 148: Human Immunodeficiency Virus Infection

Peter L. Anderson; Kristina M. Brooks; Courtney V. Fletcher

KEY CONCEPTS

KEY CONCEPTS

① Infection with human immunodeficiency virus (HIV) occurs through three primary routes: sexual, parenteral, and perinatal. Sexual intercourse, primarily receptive anal and vaginal intercourse, is the most common method for transmission.

② HIV infects cells expressing cluster of differentiation 4 (CD4) receptors, such as T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. Infection occurs via an interaction between glycoprotein 160 (gp160) on HIV with CD4 (primary interaction) and chemokine coreceptors (secondary interactions) present on the surfaces of these cells.

③ The hallmark of untreated HIV infection is profound CD4 T-lymphocyte depletion and severe immunosuppression (Acquired Immunodeficiency Syndrome [AIDS]) that puts persons with HIV at significant risk for infectious diseases caused by opportunistic pathogens. Opportunistic infections (OIs) in settings without access to antiretroviral drugs are the chief cause of morbidity and mortality associated with HIV infection.

④ The current goal of combination antiretroviral therapy (ART) is to achieve maximal and durable suppression of HIV replication, measured as the level of HIV-RNA in plasma (viral load) less than the lower limit of quantitation, usually 20 to 50 copies/mL (20×10^3–50×10^3/L). Another equally important outcome is an increase in CD4 lymphocytes because this closely correlates with the risk for developing OIs.

⑤ General principles for the management of OIs include preventing or reversing immunosuppression with ART, preventing exposure to pathogens, vaccination, prospective immunologic monitoring, primary chemoprophylaxis, treatment of acute episodes, secondary chemoprophylaxis, and discontinuation of prophylaxes following ART and subsequent immune recovery.

⑥ Clinical use of antiretroviral agents is complicated by drug-drug interactions. Some interactions are beneficial and used purposely; others may be harmful, leading to dangerously elevated or inadequate drug concentrations. For these reasons, clinicians involved in the pharmacotherapy of HIV infection must exercise constant vigilance and maintain a current knowledge of drug interactions.

⑦ Recommendations for the initial treatment of HIV advocate a minimum of two or three active antiretroviral agents from at least two drug classes. The typical regimen consists of two nucleoside/nucleotide analogs with an integrase strand transfer inhibitor (InSTI).

⑧ Inadequate suppression of viral replication allows HIV to select for antiretroviral-resistant HIV variants, a major factor limiting the ability of antiretroviral drugs to inhibit virus replication. Recommendations for treating drug-resistant HIV include choosing at least two drugs (preferably three) of different classes to which the patient's virus is susceptible. Susceptibility can be assessed using either genotypic or phenotypic resistance testing.

⑨ The reduction of viral load with ART lowers the risk of transmission to others. Additionally, pre- and post-exposure prophylaxis with antiretroviral agents in at-risk persons lowers HIV acquisition risk.

⑩ The longer life span conferred by ART has given rise to other medical issues. A wide spectrum of complications associated with older age have become common, some of which overlap with adverse effects from antiretroviral drugs. Medical management of these contemporary HIV complications is constantly evolving.

BEYOND THE BOOK

BEYOND THE BOOK

Review and complete the "HIV Infection: The Antiretroviral-Naïve Patient Level II" patient case in the *Pharmacotherapy Casebook: A Patient-Focused Approach.*

INTRODUCTION

Acquired immunodeficiency syndrome (AIDS) was first recognized in a cohort of young, previously healthy homosexual men with new-onset profound immunologic deficits, *Pneumocystis carinii* (now *Pneumocystis jirovecii*) pneumonia (PCP), and/or Kaposi's sarcoma. A retrovirus, human immunodeficiency virus type 1 (HIV-1), is the major cause of AIDS. A second retrovirus, HIV-2, is also recognized to cause AIDS, although it is less virulent, transmissible, and prevalent than HIV-1. These retroviruses are transmitted primarily by sexual contact and by contact with infected blood or blood products. Several risk behaviors for the acquisition of HIV infection have been identified in the United States, most notably the practice of anorectal intercourse and the sharing of blood-contaminated needles by injection-drug users. In many resource-limited countries, the majority of HIV transmission occurs via heterosexual intercourse and from childbearing people to their offspring. Initially, the medical management of HIV consisted of repeated treatments for opportunistic infections (OIs) and eventual palliative care. In the mid-1990s, a new era in the pharmacotherapy for HIV, known as *combination antiretroviral therapy* (ART), was born. ART consists of combinations of antiretroviral agents with different mechanisms of action that potently and durably suppress HIV replication, delay the onset of AIDS, reverse HIV-associated immunologic deficits, reduce HIV transmission, and significantly prolong survival. Modern antiretroviral drugs and ART regimens have improved tolerability and efficacy. Nevertheless, therapeutic challenges remain in the present ART era including the need for continuous adherence to medications and care, drug-drug interactions, drug-resistant HIV, acute and long-term drug toxicities, and other complications associated with a prolonged life span. Despite progress in the treatment access for this disease, large numbers of persons with HIV remain outside of care, nationally and globally. Significant efforts to develop an HIV vaccine have not been fruitful. However, prophylactic use of antiretroviral drugs effectively prevents HIV infection in persons at high risk of exposure and those exposed to the virus.

EPIDEMIOLOGY

The epidemiologic characteristics of HIV infection differ according to geographic region and depend upon the mode of transmission, governmental prevention efforts and resources, and cultural factors.[1,2]

① Infection with HIV occurs through three primary modes: sexual, parenteral, and perinatal. Sexual intercourse, primarily anal and vaginal intercourse, is the most common method for transmission. The probability of HIV transmission depends on the type of sexual exposure. The highest risk is from receptive anorectal intercourse at about 1.4 transmissions per 100 sexual acts.[3] Transmission risk is lower for receptive vaginal intercourse, and insertive sex acts have lower risk than receptive acts. Condom use reduces risk of transmission by approximately 80%.[3] Other factors that affect the probability of infection include the stage of HIV disease and viral load in the index partner. For example, transmission is significantly higher when the index partner has early or late HIV compared with asymptomatic HIV, as these disease stages are associated with higher viral loads.[3] Individuals with genital ulcers or sexually transmitted infections are at greater risk for contracting HIV. HIV incidence and prevalence are lower in cultures that advocate male circumcision, which reduces risk of male acquisition of HIV approximately 50%.[3] Casual contact with persons with HIV is not a significant risk factor for HIV transmission.

Prevention of sexual transmission has focused primarily on education that encourages safer sex practices such as use of condoms and reduction of high-risk behavior (eg, intercourse or promiscuity with partners of unknown HIV status).[4] A powerful tool for HIV prevention is combination ART for the infected individual, as this dramatically lowers viral replication and infectiousness, significantly reducing the risk of transmission to others.[3,5] In fact, the HIV scientific community has endorsed the notion that "U = U," which means undetectable (plasma HIV-RNA) = untransmittable (no HIV transmissions).[6] Another effective prevention tool is chemoprophylaxis with antiretroviral drugs, as this significantly reduces HIV acquisition risk among uninfected individuals.[7–9] A combined approach has been advocated for optimal prevention.[10] Prevention strategies under investigation include HIV vaccines and topical vaginal/rectal microbicides, such as vaginal rings containing antiretroviral drugs.[11,12]

Parenteral transmission of HIV broadly encompasses infections due to infected blood exposure from needle sticks, IV injection with used needles, receipt of blood products, and organ transplants. Use of contaminated needles or other injection-related paraphernalia by drug abusers has been the main cause of parenteral transmissions. The risk of HIV transmission from sharing needles is approximately 0.67 per 100 episodes.[3,13] Prevention strategies include stopping drug use, obtaining needles from credible sources (eg, pharmacies), never reusing or sharing any paraphernalia, using sterile procedures in all injecting activities, and safely disposing of used paraphernalia.[10]

Before widespread screening, HIV was readily transmitted in blood products.[13] However, blood and tissue products in the healthcare system are now rigorously screened for HIV. The estimated risk for receiving contaminated blood or blood products in the United States is well below 1:2.3,000,000 and that for receiving a contaminated tissue transplant is 1:55,000.[14,15] Healthcare workers have a small but definite occupational risk of contracting HIV through accidental exposure. Most cases of occupationally acquired HIV have been the result of a percutaneous needle stick injury, which carries an estimated 0.3% risk of transmitting HIV.[3,16] Mucocutaneous exposures (eg, blood splash in eyes, mouth, or nose) carries a transmission risk of approximately 0.09%.[16] Significant risk factors for seroconversion with a needle stick include deep injury, injury with a device visibly contaminated with blood, and advanced HIV disease in the index patient (high viral load). The risk of transmission from a healthcare worker with HIV to a patient is extremely remote. Comprehensive medical guidelines, including antiretroviral drug prophylaxis, have been developed to minimize the hazard of HIV transmission for healthcare workers and persons exposed by rape or other means.[13,16]

Perinatal infection, or vertical transmission, is the most common cause of pediatric HIV infection. Most infections occur during or near to the time of birth, although a fraction can occur in utero.[2] The risk of mother-to-child transmission is approximately 25% in the absence of ART. Factors that increase the likelihood of vertical transmission include prolonged rupture of membranes, chorioamnionitis, genital infection during pregnancy, preterm delivery, vaginal delivery, birth weight less than 2.5 kg, illicit drug use and cigarette smoking during pregnancy, and high maternal viral load.[17] Breast-feeding in the absence of ART can also transmit HIV. The frequency of breast milk transmission is approximately 5% to 10% in the first 6 months and 15% to 20% through 18 to 24 months without interventions to reduce transmission.[18] High levels of virus in breast milk and in the mother are associated with higher risk of transmission. Formula feeding prevents breast milk transmission of HIV but may not improve mortality from other causes early in life in resource limited settings.[19] In the United States, mothers with HIV are recommended not to breastfeed.[19] A separate and comprehensive set of medical guidelines including antiretroviral drug prophylaxis have been developed to minimize the risk of mother-to-child HIV transmission.[19]

Persons with HIV infection are broadly categorized as those living with HIV and those with an AIDS diagnosis (stage 3). An AIDS diagnosis is made when the presence of HIV is laboratory-confirmed and the CD4 (T-helper cell) count drops below 200 cells/mm^3 (0.2 × 10^9/L) for those aged 6 years or older, or after an AIDS indicator condition is diagnosed.[20] Further distinctions regarding the stage of HIV and AIDS (stage 3) are given in the revised Centers for Disease Control and Prevention (CDC) surveillance case definition (Table 148-1).[20] In the United States, the CDC estimates HIV epidemiology using models that rely on surveillance data from state and local health departments.[10] Using these models about 1.2 million individuals are living with HIV (all stages) in the United States.[10] Approximately 13% of persons with HIV are unaware of their infection and only approximately 50% of those who are aware of their infection are consistently retained in care. Therefore, a about half of persons with HIV are not receiving ART regularly, which significantly contributes to the ongoing transmission of HIV infection in the United States, totaling 36,800 new infections per annum.[21,22]

TABLE 148-1

Surveillance Case Definition for HIV Infection Stage Based on CD4+ T-lymphocyte Counts, United States, 2014

	Age on date of CD4+ T-lymphocyte test					
	<1 year		**1-5 years**		**≥6 years**	
Stage	Cells/µL (×10^6/L)	%	Cells/µL (×10^6/L)	%	Cells/µL (×10^6/L)	%
1	≥1,500	≥34	≥1,000	≥30	≥500	≥26
2	750-1,499	26-33	500-999	22-29	200-499	14-25
3 (AIDS)	<750	<26	<500	<22	<200	<14

AIDS-defining conditions	
Bacterial infections, multiple or recurrent (specific to children <6 years)	
Candidiasis of bronchi, trachea, or lungs	Lymphoma, Burkitt
Candidiasis, esophageal	Lymphoma, immunoblastic
Cervical cancer, invasive (specific to adults, adolescents, children >6 years)	Lymphoma, primary, or brain
Coccidioidomycosis, disseminated or extrapulmonary	*Mycobacterium avium* complex or *Mycobacterium kansasii*, disseminated or extrapulmonary
Cryptococcosis, extrapulmonary	*Mycobacterium tuberculosis*, any site (pulmonary or extrapulmonary)
Cryptosporidiosis, chronic intestinal (duration >1 month)	*Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
Cytomegalovirus disease (other than liver, spleen, or nodes), onset at age > 1 month	*Pneumocystis jirovecii* pneumonia (PCP)
Cytomegalovirus retinitis (with loss of vision)	Pneumonia, recurrent (specific to adults, adolescents, children >6 years)
Encephalopathy, HIV-related	Progressive multifocal leukoencephalopathy
Herpes simplex: chronic ulcer(s) (duration >1 month); or bronchitis, pneumonitis, or esophagitis, onset at age > 1 month	*Salmonella* septicemia, recurrent Toxoplasmosis of brain, onset at age >1 month Wasting syndrome due to HIV
Histoplasmosis, disseminated or extrapulmonary Isosporiasis, chronic intestinal (duration >1 month) Kaposi's sarcoma	

Data from Reference [20].

The epidemic in the United States was initially established in men who have sex with men (MSM), and this population continues to be prominently affected by HIV, accounting for 65% of new cases.[21]

Heterosexual transmissions accounted for approximately 23% of new cases and approximately 65% of these are women. Injection-drug use makes up about 7% of new cases. For women, the main risk factor for transmission is heterosexual intercourse (~85% of cases) and injection-drug use (~15% of cases). For men, the main risks are MSM (~81%), heterosexual sex (~10%), and injection-drug use (~10%).[21] Black and Hispanic communities are disproportionately affected by HIV infection. Of new infections in recent years, 42% were in Black persons and 29% were in Hispanic persons, although these populations only make up 12% and 18% of the US population, respectively. A relatively large proportion of these populations are not well linked to appropriate prevention, care, and treatment services, which represents a significant public health challenge.[10]

The number of individuals living with HIV globally has risen to 37.6 million persons.[1,23] Increases are due to longer lifespans due to wider implementation of ART worldwide. This has reduced the death rate and new infection rate. For example, the peak number of new infections was 3 million per year in 1997 and this has declined to 1.5 million in 2020. New infections in children (mostly due to perinatal transmission) have declined by 52% between 2010 and 2020, and overall deaths have declined by approximately 59% since 2004. Nevertheless, approximately 690,000 people succumbed to HIV in 2019 and HIV is still a major contributor to the global burden of disease.[1,23] The highest concentration of HIV cases in the world is in sub-Saharan Africa, where approximately 26 million people are infected. However, new infections have declined there by approximately 25% to 38% since 2010, depending on the region. Heterosexual transmission is the most common mode of transmission in sub-Saharan Africa and worldwide. Women in sub-Saharan Africa and resource-limited countries are at disproportionately high risk for acquiring HIV because of biological and cultural factors that foster HIV transmission, such as limited ability to negotiate condom use. Other important epidemiologic features of the HIV epidemic include growing incidence among injection-drug users in North Africa and the Middle East, as well as some regions of Eastern Europe and Central Asia (eg, Russia and Ukraine).[23]

ETIOLOGY

HIV is an enveloped single-stranded RNA virus and a member of the Lentivirinae (*lenti*, meaning "slow") subfamily of retroviruses. Lentiviruses are characterized by their indolent infectious cycle. There are two related but distinct types of HIV: HIV-1 and HIV-2. HIV-2, found mostly in western Africa, consists of seven phylogenetic lineages designated as subtypes (clades) A through G. Four groups of HIV-1 are recognized: M (main or major), N (non-M, non-O), O (outlier), and P (pending the identification of further cases).[2] The nine subtypes of HIV-1 group M are identified as A through D, F through H, J, and K. Mixtures of subtypes are referred to as *circulating recombinant forms.* Group M, subtype B, is primarily responsible for the epidemic in North America and western Europe.[24]

HIV in humans was the result of a cross-species transmission (zoonosis) from primates infected with simian immunodeficiency virus (SIV).[24] Phylogenetic and geographic relationships suggest that HIV-2 arose from SIV that infects sooty mangabeys, and HIV-1 groups M and N arose from SIVcpz, a virus that infects chimpanzees (*Pan troglodytes troglodytes*). Groups O and P may have arisen from an SIV variant that infects wild gorillas. Cultural practices, such as preparation and eating of bush meat or keeping animals as pets, may have allowed the virus to cross from primates to humans. The earliest known human infection with HIV has been traced to central Africa in 1959, but cross-species transmissions probably date back to the early 1900s.[24] Modern transportation, promiscuity, and drug use have caused the rapid and continued spread of the virus within the United States and throughout the world. This chapter focuses on HIV-1 group M, which is the predominant strain likely to be encountered in the western world.

PATHOGENESIS

② Understanding the life cycle of HIV (Fig. 148-1) is necessary because the current strategies used for HIV treatment target points in this cycle. Once HIV enters the human body, the outer glycoprotein (gp160) on its surface, which is composed of two subunits (gp120 and gp41), has affinity for CD4 receptors, which are proteins present on the surface of T-helper lymphocytes, monocytes, macrophages, dendritic cells, and brain microglia. The gp120 subunit is responsible for CD4 binding. Once initial binding occurs, the intimate association of HIV with the cell is enhanced by further binding to chemokine coreceptors. The two major chemokine receptors used by HIV are chemokine (C–C motif) receptor 5 (CCR5) and chemokine (C–X–C motif) receptor 4 (CXCR4). HIV isolates may contain a mixture of viruses that target one or the other of these coreceptors, and some viral strains may be dual-tropic (ie, can use both coreceptors). The HIV strain that preferentially uses CCR5, referred to as R5 viruses, is macrophage-tropic and typically implicated in most cases of sexually transmitted HIV.[25] Individuals with a common 32-base-pair deletion in the CCR5 gene are protected from progression of HIV disease, and those who are homozygous for the 32-base-pair deletion have a degree of resistance to acquisition of HIV-1.[26] The HIV strain that targets CXCR4, designated X4 virus, is T-cell-tropic and often is predominant in the later stage of disease. CD4 and coreceptor attachment of HIV to the cell promotes membrane fusion, which is mediated by gp41, and finally internalization of the viral genetic material and enzymes necessary for replication.

After internalization, the viral protein shell surrounding the nucleic acid (capsid) undergoes a disassembly process in preparation for replication.[27] The genetic material of HIV is positive-sense single-stranded RNA; the virus must transcribe this RNA into DNA (transcription normally occurs from DNA to RNA; HIV works backward, hence the name *retrovirus*). To do so, HIV is equipped with the unique enzyme RNA-dependent DNA polymerase (reverse transcriptase). HIV reverse transcriptase first synthesizes a complementary strand of DNA using the viral RNA as a template. The RNA portion of this DNA-RNA hybrid is then partially removed by ribonuclease H (RNase H), allowing HIV reverse transcriptase to complete the synthesis of a double-stranded DNA molecule. The fidelity of HIV reverse transcriptase is poor, and many mistakes are made during the process. These errors in the final DNA product contribute to the rapid mutation of the virus, which enables the virus to evade the immune response (thus complicating vaccine development), and promotes the evolution of drug resistance during partially suppressive therapy. Following reverse transcription, the final double-stranded DNA product migrates into the nucleus and is integrated into the host cell chromosome by integrase, another enzyme unique to HIV.

The integration of HIV into the host chromosome is critically important. Most notably, HIV can establish a persistent, latent infection, particularly in long-lived cells of the immune system such as memory T lymphocytes. The virus is effectively hidden in these cells until the cells become activated, and this characteristic has greatly complicated efforts to cure HIV infection.[28] It also necessitates continuous ART therapy because virus reemerges from this reservoir if therapy is suspended.

After integration, HIV preferentially replicates in activated cells. Activation by antigens, cytokines, or other factors stimulates the cell to produce nuclear factor kappa B (NF-κB), an enhancer-binding protein. NF-κB normally regulates the expression of T-lymphocyte genes involved in growth but also can inadvertently activate replication of HIV.[28] HIV encodes six regulatory and accessory proteins, such as Tat, Nef, Rev, Vpu, Vif, and Vpr, which enhance replication and inhibit innate immunity. For example, the Tat protein is a potent amplifier of HIV gene expression; it binds to a specific RNA sequence of HIV that initiates and stabilizes transcription elongation.[28] Vif is a viral protein that binds human APOBEC 3G, a cytidine deaminase that disrupts the virus' genetic code by converting viral RNA cytosine to uracil, thereby providing innate cellular immunity.[29] Vpu inhibits tetherin, a human cellular membrane protein that prevents release of virus particles after budding from infected cells. Assembly of new viral particles occurs in a stepwise manner beginning with the coalescence of HIV proteins beneath the host cell lipid bilayer. The nucleocapsid is subsequently formed with viral single-stranded RNA and other components packaged inside. Once packaged, the virion then buds through the plasma membrane, acquiring the characteristics of the host lipid bilayer. After the virus buds, the maturation process begins. Within the virion, protease, another enzyme unique to HIV, cleaves large precursor polypeptides (gag and gag-pol) into functional proteins (capsid, protease, reverse transcriptase, and integrase) that are necessary to produce a complete and infectious virus. Without this enzyme, the virion is immature and unable to infect other cells. Capsid is key to this final maturation process, as well as many other roles in the HIV life-cycle such as facilitating reverse transcription, intracellular transport, nuclear entry, and integration.[30] Thus, potent capsid inhibitors are under development and soon will join the antiretroviral armamentarium.

The natural history of HIV infection exhibits three general phases: acute, chronic, and terminal (AIDS). Initial rounds of HIV replication during acute infection take place largely in the mucosal CD4+, CCR5+ T-cell pools in the gut, resulting in a massive CD4 T-cell depletion in these tissues.[31] Cells are destroyed by various mechanisms, including cell lysis from newly budding virions, cytotoxic T-lymphocyte-induced cell killing, and induction of apoptosis. Following this destruction of the mucosal CD4 T-cell pool, which lasts for 2 to 3 weeks, a state of heightened immune activation ensues during the chronic infection phase, which can last for several years. The activated state is characterized by high levels of activation markers on circulating T cells (eg, HLA-DR and CD38) and proinflammatory cytokines, and may result from HIV antigen as well as translocation of microbial antigens from the T-cell-depleted gut mucosa. Heightened activation enables further HIV replication and ultimately leads to continued depletion of CD4+, CCR5+ T cells. HIV-1 exhibits a high turnover rate during this chronic phase, with an estimated 10 billion new viruses produced each day.[32] More than 99% of these viruses are produced in newly infected activated cells. Nevertheless, for much of the chronic phase, the immune system is able to operate well enough to prevent overt OIs that herald AIDS. However, the depletion of CD4 cells and continuous cellular activation eventually lead to a final collapse of the immune system, or AIDS. HIV may use the CXCR4 coreceptor during this last phase of infection, and these viruses infect a broader range of CD4 cells (naïve and central-memory) speeding the disease progression. It is this unrelenting destruction of CD4 cells that causes the profoundly compromised immune system and AIDS.

DIAGNOSIS

Detection of HIV and Surrogate Markers of Disease Progression

HIV is diagnosed through a multi-step process.[33] The presence of HIV infection is screened with an enzyme-linked immunosorbent assay (ELISA), which detects antibodies against HIV-1. Although ELISA has been the mainstay of HIV screening for decades, the technology has been evolving to detect infection earlier in the time course of the disease.[34] Older ELISA tests detected IgG (second-generation tests), but more modern tests detect IgG and IgM (third-generation tests) and may further include detection of p24 antigen, an early marker of infection (fourth-generation tests). These technological advances enable earlier detection of HIV by as much as 15 to 20 days compared with older second-generation tests. ELISA tests are generally highly sensitive (greater than 99%) and highly specific (greater than 99%), but rare false-positive results can occur particularly in those with autoimmune disorders.[33] False-negative results also occur and may be attributed to the “window period” before adequate production of antibodies or antigen. This “window period” between HIV acquisition and detection of HIV with fourth- and third-generation tests is approximately 2 and 3 weeks, respectively.[33] Positive screening tests are confirmed with another enzyme immunoassay to specify if the antibodies are to HIV-1 versus HIV-2 (although HIV-2 is rare in the United States, this step ensures proper diagnosis and treatment). If this follow-up assay is indeterminant or negative, an HIV nucleic acid test is performed for definitive diagnosis. HIV-RNA is the earliest indicator of infection, detectable ~10 days from acquisition and about 1 week before fourth-generation tests.[34] Several point-of-care screening kits are available for serum, plasma, whole blood, or oral fluids. While oral fluid tests are convenient, they are not as sensitive as blood assays, which may result in false-negatives early in infections; this is a particular disadvantage in the setting of HIV testing prior to initiating or continuing preexposure prophylaxis (PrEP).[34] Clinicians should be aware that HIV acquisition during PrEP may be associated with prolonged HIV suppression and delayed antibody expression.[35] HIV testing is recommended when HIV infection is suspected because of symptoms and/or high-risk behavior.[36] Additionally, the CDC recommends routine HIV screening at least once in all healthcare settings in all persons 13 to 64 years, a policy called “opt-out” testing.[37] A focus of the recommendations is to screen persons at high risk of HIV infection (eg, MSM) at least annually and to screen pregnant persons while they are in care. The policy states that consent for medical care will imply consent for HIV testing; however, the person must be informed of the test and can opt out of taking it. Because states may have different HIV consent laws, the local requirements for HIV testing should be consulted. The rationale for the opt-out strategy is to diagnose those who unknowingly carry HIV so as to initiate ART early, leading to improved prognosis and reduced forward transmissions.

Once diagnosed, HIV disease is monitored primarily by two surrogate biomarkers, viral load and CD4 cell count.[38] The viral load test quantifies the degree of viremia by measuring the number of copies of viral RNA (HIV-RNA) in the plasma. Methods for determining HIV-RNA include reverse-transcription polymerase chain reaction (RT-PCR), branched-chain DNA, transcription-mediated amplification, and nucleic acid sequence-based assay. RT-PCR is used more widely than the other techniques.[34] Irrespective of the method used, viral load is reported as the number of viral RNA copies per milliliter of plasma. Each assay has its own lower limit of quantitation, and results can vary from one assay method to the other; therefore, the same assay method should be used consistently for each patient. Reductions in viral load often are reported in base 10 logarithm. For example, if a patient presents initially with a viral load of 100,000 copies/mL (10^5 copies/mL or 10^8 copies/L) and subsequently has a viral load of 10,000 copies/mL (10^4 copies/mL or 10^7 copies/L), the decrease is 1 $\log_{10}$. Given that HIV-RNA varies within a patient, a perceptible clinical response is generally considered when the decline in viral load is more than 0.5 $\log_{10}$.[38] Viral load is a major prognostic factor for disease progression, CD4 count decline, and death.[38] It is also the predominant way to assess the effectiveness of treatment.

Because HIV attacks and leads to the destruction of cells bearing the CD4 receptor, the number of CD4 lymphocytes (T-helper cells) in the blood is a critical surrogate marker of disease progression and immune system status.[38] The normal adult CD4 lymphocyte count ranges from 500 to 1,600 cells/mm^3 (0.5×10^9–1.6×10^9/L), or 40% to 70% (0.4-0.7) of total lymphocytes. CD4 counts in children are age dependent, with younger children having higher CD4 counts (see Table 148-1). The hallmark of HIV disease is depletion of CD4 cells and the associated development of OIs and malignancies, especially at lower CD4 cell counts.

CLINICAL PRESENTATION

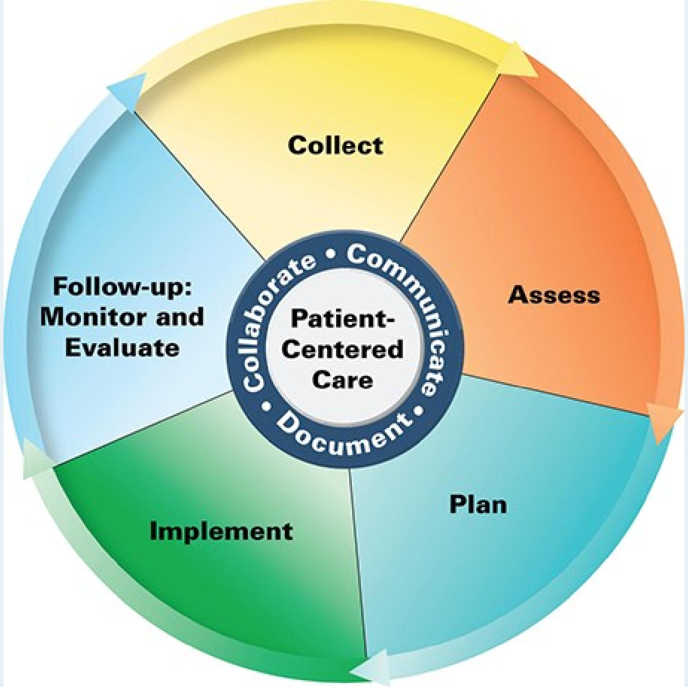
③ Clinical presentation of primary HIV infection varies, but most patients (50%-90%) have an acute retroviral syndrome or mononucleosis-like illness, presumably due to the host immune response to the virus (ie, "cytokine storm").[39] Although many of these symptoms are nonspecific (eg fever, headache, fatigue, lymphadenopathy, pharyngitis, rash), the presence of aseptic meningitis, oral or genital ulcers, and leukopenia should raise suspicion of acute HIV infection in the setting of a potential exposure. Symptoms often last 2 weeks, and hospitalization may be required for a small fraction of patients. Primary infection is associated with a high viral load (more than 10^6 copies/mL [10^9/L]) and a precipitous drop in CD4 cells. After several weeks, an immune response is mounted, the amount of HIV-RNA in plasma falls substantially, CD4 cells rebound slightly, and symptoms resolve gradually. However, as described above, this clinically latent period is not virologically latent because HIV replication is continuous (~10 billion viruses per day) and immune system destruction is ongoing. A steady decrease in CD4 cells (~50 cells/μL [0.05×10^9/L] per year) is the most measurable aspect of this immune system deterioration during the asymptomatic phase. Plasma viral load, on the other hand, is stabilized at a particular level or "set point." The set point correlates strongly with the CD4 cell decline and time to AIDS and morbidity. For example, prior to ART, the Multicenter AIDS Cohort Study measured viral load in 1,604 HIV-positive men and followed them for as long as 11 years. The CD4 cell count decline was approximately twice as fast in those with HIV-RNA above 30,000 copies/mL (30×10^6/L) compared with those with HIV-RNA less than or equal to 500 copies/mL (500×10^3/L) and mortality rates (within 6 years) were 69.5% versus 0.9%, respectively.[40] Thus, a higher viral set point is associated with faster disease progression and poorer prognosis. Not all individuals infected with HIV progress to AIDS—these so-called "long-term nonprogressors" (also known as "elite controllers") may be infected with a defective virus (eg, Nef-deficient HIV) or may have an intrinsic ability to resist infection (eg, CCR5 mutation).

Most children born with HIV are asymptomatic. On physical examination, children often present with nonspecific signs, such as lymphadenopathy, hepatomegaly, splenomegaly, failure to thrive, weight loss or unexplained low birth weight (in prenatally exposed infants), and fever of unknown origin.[41] Laboratory findings include anemia, hypergammaglobulinemia (primarily IgA and IgM), altered mononuclear cell function, and altered T-cell subset ratios. Of note, the normal range for CD4 cell counts in young children is much different from the range in adults (Table 148-1). Children have different susceptibility and/or exposures to OIs compared with adults. Bacterial infections, including *Streptococcus pneumoniae*, *Salmonella* spp., and *Mycobacterium tuberculosis*, may be more prevalent in children with AIDS than in adults with the disease. Kaposi's sarcoma is rare in children. Children with HIV infection may develop lymphocytic interstitial pneumonitis without evidence of *P. jirovecii* or other pathogens on lung biopsy.

Some children (~25%) will progress to AIDS rapidly within the first year of life. A presentation of serious OIs such as *P. jirovecii* pneumonia, encephalopathy, failure to thrive, and a precipitous drop in CD4 cells are common in these infants. General management of children with HIV involves principles similar to those used for adults: ART, treatment and prophylaxis of OIs, and supportive care.[42,43]

PATIENT CARE PROCESS

Patient Care Process for Human Immunodeficiency Virus (HIV)



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, sex, race, ethnicity, contraception methods, or pregnancy intentions)
- Patient medical history (eg, HBV, HCV, STIs, other chronic/acute illnesses)
- Previous HIV history (mode of transmission, date of diagnosis, nadir CD4$^+$ T-cell count, history of previous opportunistic infections, history of antiretroviral resistance)
- Social history (eg, drug use, sexual history, high-risk behaviors)
- Current prescription and nonprescription medications including herbal products, dietary supplements, and any previous antiretroviral regimens
- Objective data
  - HIV screening and confirmatory tests
  - HIV-RNA and CD4$^+$ cell count
  - Baseline antiretroviral resistance testing
  - HLA-B*5701 testing
  - Complete blood count, basic metabolic panel, liver function panel, sexually transmitted infection screening

Assess

- Understanding of disease state and goals of treatment
- Access to ART (ie, insurance and co-pays)

- Willingness to start and adhere to ART
- Potential drug-drug interactions
- Any contraindications or concerns related to recommended ART regimens (eg, chronic kidney disease, ART resistance, HLA-B*5701 genotype, history of cardiovascular disease, hyperlipidemia, uncontrolled psychiatric illness, pregnancy or desire to become pregnant, history of multiple bone fractures, or severe osteoporosis)
- Need for opportunistic infection prophylaxis (ie, CD4$^+$ cell count)

Plan*

- ART regimen including specific agents, dose, frequency, administration (eg, food requirements), drug-drug interactions (see Tables 148-2 and 148-3)
- Monitoring parameters including efficacy (eg, HIV-RNA, CD4$^+$ cell count) and safety (eg, adverse effects, SCr, LFTs, CBC)
- Follow-up every 3 months until HIV-RNA is undetectable
- Patient education (eg, purpose of treatment, importance of adherence, transmission risk, drug- specific information; see Table 148-3)
- Referrals to other providers when appropriate (eg, behavioral health, social work)

Implement*

- Provide patient education regarding all elements of treatment plan
- Emphasize need for adherence to ART regimen and provide resources that can be used to maximize adherence
- Schedule follow-up for assessment of ART efficacy, safety, and adherence

Follow-Up: Monitor and Evaluate

- Therapeutic efficacy (ie, reduction in HIV-RNA) and safety
- Restoration of immune function (ie, increasing CD4$^+$ cell count)
- Presence of adverse effects (eg, GI upset, headache, nausea)
- Renal and hepatic function
- Patient access and adherence to ART

Collaborate with patient, caregivers, and other healthcare professionals.[*]

TREATMENT

Desired Outcomes

④ The central goals of ART are to decrease morbidity and mortality, improve quality of life, restore and preserve immune function, and prevent further transmission.[38] The most important and effective way to achieve these goals is maximal and durable suppression of HIV replication, which is interpreted as plasma HIV-RNA less than the lower limit of quantitation (ie, undetectable; usually less than 20 or 50 copies/mL [20×10^3 or 50×10^3/L]). Such a profound reduction in HIV-RNA is associated with reduced transmissions and long-term response to therapy (ie, durability), as well as increases in CD4 lymphocytes that closely correlate with a reduced risk for developing OIs. While undetectable HIV-RNA almost always corresponds with a rise in

CD4 lymphocytes, some patients respond virologically or immunologically without the other.

General Approach to Treatment

5 Contemporary combinations of two or three active antiretroviral agents from two pharmacologic classes potently inhibit HIV replication to undetectable plasma levels, prevent and reverse immune deficiency, and substantially decrease morbidity and mortality—constituting the modern ART era.[44] Principles that serve as a guide for the clinical use of antiretroviral agents include[45]:

1. Ongoing HIV replication leads to immune system damage and progression to AIDS. HIV infection is always harmful, and true long-term survival free of clinically significant immune dysfunction is unusual.
2. Plasma HIV-RNA levels indicate the magnitude of HIV replication and its associated rate of CD4 cell destruction, whereas CD4 cell counts indicate the extent of HIV-induced immune damage already suffered.
3. Use of potent combination ART to suppress HIV replication to below the levels of detection of sensitive plasma HIV-RNA assays limits the potential for selection of antiretroviral-resistant HIV variants, the major factor limiting the ability of antiretroviral drugs to inhibit virus replication and delay disease progression. Therefore, maximum achievable suppression of HIV replication should be the goal of therapy.
4. The most effective means for accomplishing durable suppression of HIV replication is simultaneous initiation of combinations of effective anti-HIV drugs with which the patient has not been treated previously and that are not cross-resistant with antiretroviral agents with which the patient has been treated previously.
5. Each of the antiretroviral drugs used in combination therapy regimens always should be used according to optimal schedules and dosages.
6. The available effective antiretroviral drugs are limited in number and mechanism of action, and cross- resistance between specific drugs has been documented. Therefore, any change in ART increases future therapeutic constraints.
7. People of child-bearing potential should receive optimal ART regardless of pregnancy status.
8. The same principles of ART apply to both children and adults with HIV, although treatment of children with HIV involves unique pharmacologic, virologic, and immunologic considerations.
9. Persons with acute primary HIV infections should be treated with combination ART to suppress virus replication to levels below the limit of detection of sensitive plasma HIV-RNA assays.

The extent to which these principles will continue to stand the test of time is unknown; new information on the pathogenesis and treatment of HIV accrues constantly. As of October 2021, 34 antiretroviral compounds have been approved by the FDA; six (amprenavir, delavirdine, didanosine, indinavir, stavudine and zalcitabine) have since been removed from the United States market. Table 148-2 presents the state of the art for treatment of persons with HIV as of October 2021.[38] Treatment is recommended for all persons with HIV regardless of CD4 lymphocyte count, as long as the patient is ready to adhere to therapy. Urgent indications for therapy include pregnancy, history of AIDS-defining illness, CD4 counts below 200 cells/mm^3 (0.2 × 10^9/L), HIV-associated nephropathy, HIV/hepatitis C virus coinfection, and/or HIV/hepatitis B virus coinfection.

TABLE 148-2

Treatment of Human Immunodeficiency Virus Infection: Antiretroviral Regimens Recommended as Initial Therapy for Persons with HIV

	Regimen	Selected Limitations
Recommended Initial Regimens for Most Persons with HIV		
InSTI based	Bictegravir + tenofovir alafenamide fumarate + emtricitabine (coformulated) (AI)	Not recommended if CrCl <30 mL/min (0.5 mL/s); interactions with polyvalent cations; bictegravir inhibits creatinine secretion increasing serum creatinine (distinguish vs renal dysfunction); CNS/psychiatric side effects (primarily in those with pre-existing conditions)

	Dolutegravir + abacavir + lamivudine (coformulated) (AI)	Only if HLA-B*5701 negative; do not use in chronic hepatitis B infection; interactions with polyvalent cations; dolutegravir inhibits creatinine secretion increasing SCr (distinguish vs renal dysfunction); CNS/psychiatric side effects (primarily in those with pre-existing conditions)
	Dolutegravir + (tenofovir disoproxil fumarate or tenofovir alafenamide fumarate)[a] + (emtricitabine or lamivudine)[b] (AI)	Same as above without HLA-B*5701 negative requirement
	Dolutegravir + lamivudine (AI)	Do not use if HIV VL ≥500,000 copies/mL (500 x 10^6/L), chronic hepatitis B infection or hepatitis B infection status is unknown, or if HIV genotype is unavailable or shows resistance to either component
Recommended initial regimens in certain clinical situations (some potential disadvantages vs previous category)		
InSTI based	Elvitegravir + cobicistat + tenofovir disoproxil fumarate + emtricitabine (coformulated) (BI)	Initiation not recommended if CrCl <70 mL/min (1.17 mL/s); food requirement; interactions with polyvalent cations; CYP3A4 drug interactions; cobicistat inhibits creatinine secretion increasing SCr (distinguish vs renal dysfunction); CNS/psychiatric side effects (primarily in those with pre-existing conditions)
	Elvitegravir + cobicistat + tenofovir alafenamide fumarate + emtricitabine (coformulated) (BI)	Not recommended if CrCl <30 mL/min (0.5 mL/s); otherwise, same as above
	Raltegravir + (tenofovir disoproxil fumarate or tenofovir alafenamide) + (emtricitabine or lamivudine) (BI for tenofovir disoproxil fumarate+ (emtricitabine or lamivudine)[b]; BII for tenofovir alafenamide + emtricitabine)	Raltegravir can be dosed once or twice daily depending on the formulation; interactions with polyvalent cations; creatine kinase increases; TDF/FTC not recommended if CrCl <50 mL/min (0.83 mL/s) and TAF/FTC not recommended if CrCl <30 mL/min (0.5 mL/s); CNS/psychiatric side effects (primarily in those with pre-existing conditions)
HIV PI based[c]	Atazanavir + ritonavir (or cobicistat) + (tenofovir disoproxil fumarate or tenofovir alafenamide fumarate)[a] + (emtricitabine or lamivudine) (BI)	GI side effects; food requirement; CYP3A4 drug interactions; hyperbilirubinemia leading to drug discontinuation, especially in those with Gilbert's syndrome; use of cobicistat with TDF/FTC not recommended if CrCl <70 mL/min (1.17 mL/s); use of TAF/FTC not recommended if CrCl <30 mL/min (0.5 mL/s); cobicistat inhibits creatinine secretion increasing SCr (distinguish vs renal dysfunction)
	Darunavir + (ritonavir or cobicistat) + (tenofovir disoproxil fumarate or tenofovir alafenamide)[a] + (emtricitabine or lamivudine)b (AI)	Rash (darunavir has sulfonamide moiety); GI side effects; food requirement; CYP3A4 drug interactions; use of cobicistat with TDF/FTC not recommended if CrCl <70 mL/min (1.17 mL/s); use of TAF/FTC not recommended if CrCl <30 mL/min (0.5 mL/s); cobicistat inhibits creatinine secretion increasing serum creatinine (distinguish vs renal dysfunction); see issues above
	Darunavir + ritonavir (or cobicistat) + abacavir + lamivudine (BII)	Only if HLA-B*5701 negative; see issues above
NNRTI based	Doravirine + tenofovir disoproxil fumarate + lamivudine (coformulated) (BI)	Not recommended if CrCl <50 mL/min (0.83 mL/s); CNS side effects
	Doravirine + tenofovir alafenamide + emtricitabine (BIII)	TAF/FTC not recommended if CrCl <30 mL/min (0.5 mL/s); CNS side effects

	Efavirenz + tenofovir disoproxil fumarate + (emtricitabine or lamivudine)[b] (coformulated) (BI)	CNS side effects with efavirenz; CYP450 drug interactions; empty stomach dosing before bed; not recommended if CrCl <50 mL/min (0.83 mL/s)
	Efavirenz + tenofovir alafenamide + emtricitabine (BII)	CNS side effects with efavirenz; CYP450 drug interactions; empty stomach dosing before bed; TAF/FTC not recommended if CrCl <30 mL/min (0.5 mL/s)
	Rilpivirine + (tenofovir disoproxil fumarate or tenofovir alafenamide)[a] + emtricitabine (coformulated) (BI for TDF and BII for TAF)	Not recommended when HIV-RNA>100,000 copies/mL (100 x 10^6/L) or CD4 <200 cells/µL (0.2 x 10^9/L); no proton-pump inhibitors (rilpivirine); food requirement; antacid interactions
If abacavir and tenofovir cannot be used	Dolutegravir + lamivudine (AI)	Do not use if HIV VL ≥500,000 copies/mL (500 x 10^6/L), chronic hepatitis B infection or hepatitis B infection status is unknown, or if HIV genotype is unavailable or shows resistance to either component
	Darunavir + ritonavir + raltegravir (CI)	Only if HIV-RNA < 100,000 copies/mL (100 x 10^6/L) and CD4 > 200 cells/mm^3 (0.2 x 10^9/L); raltegravir must be dosed twice daily; do not use in chronic hepatitis B infection
	Darunavir + ritonavir + lamivudine (CI)	Do not use in chronic hepatitis B infection

Selected regimens or components that should not be used at any time

Regimen or component	**Comment**
Monotherapy with any single agent (AI)	Inferior virologic efficacy; risk of virologic rebound and resistance
Any NRTI only regimen (AI)	Inferior virologic efficacy
Unboosted PIs (ie, darunavir) (AII)	Inadequate bioavailability
Etravirine + unboosted PIs (AII)	Possible induction of PI metabolism, doses not established
Nevirapine in ARV naïve with higher CD4 counts (>250 cells/µL [0.25 × 10^9/L] for women, >400 cells/µL [0.4 × 10^9/L] for men) (BI)	High incidence of symptomatic hepatotoxicity

[a] TAF and TDF are prodrugs of tenofovir with differing pharmacology and safety profiles. Safety, cost, and access should be considered when deciding between which form to use.

Evidence-based rating definition. Rating strength of recommendation—A: Strong recommendation. B: Moderate recommendation. C: Optional recommendation. Rating Quality of Evidence Supporting the Recommendation—I: Evidence from randomized, controlled trials. II: Evidence from at least one well-designed clinical trial without randomization or observational cohorts with long-term clinical outcomes. III: Expert opinion. Lamivudine and emtricitabine are considered interchangeable endpoints.

[b] Emtricitabine and lamivudine are interchangeable

[c] Boosted darunavir is generally preferred over boosted atazanavir.

Data from Reference [38].

The optimal time to initiate therapy in chronic HIV infection was a matter of debate. The main arguments for postponing therapy were the concern for cumulative drug toxicity and trepidation for drug resistance and loss of therapeutic options. These concerns were well-founded when older drugs such as lopinavir/ritonavir, stavudine, zidovudine, indinavir, and efavirenz were the mainstay of therapy. Today, the availability of newer medications with different mechanisms of action (eg, InSTIs), significantly improved adverse event profiles, and the convenience of single tablet regimens help to mitigate these issues. Two large randomized controlled trials helped address the issue of whether initiating therapy immediately or waiting for a lower CD4 count]) provided clinical benefit.[46,47] In the START trial, immediate ART resulted in significantly fewer serious AIDS events (HR 0.28, 95% CI 0.15-0.50) and non-AIDS events (HR 0.61, 0.38-0.97) as compared with delaying ART until CD4 count fell below 350 cells/μL (0.35 x 10^9/L).[46] The TEMPRANO study also found that immediate ART resulted in fewer deaths or severe HIV-related illnesses as compared with deferred ART (HR among patients with a baseline CD4 greater than or equal to 500 cells/μL [0.5 × 10^9/L], 0.56; 95% CI, 0.33-0.94).[47] Immediate ART and subsequent suppressed viral load is also known to substantially prevent ongoing HIV transmissions compared with delayed ART.[48] Taken together, these studies provide high-quality evidence that untreated HIV is harmful even at high CD4 counts and immediate ART confers individual- and population-level benefit compared with delayed ART. Major policy-makers, including the WHO and US Department of Health and Human Services (DHHS), now recommend immediate ART regardless of CD4 count.[38,49]

More recent efforts have shifted towards immediate or rapid ART initiation, meaning that antiretroviral therapy is started on the same day or within a few days to weeks of HIV diagnosis. This strategy generally increases ART uptake, improves engagement and retention in HIV care, reduces time to viral suppression, and improves overall rates of those on ART with viral suppression. Several randomized controlled studies in resource-limited settings have shown marked improvements in these outcomes,[50] and prospective observational studies within the United States have shown similar patterns.[51] However, this approach requires the alignment of several resources within a short time frame and thus may be logistically challenging to implement in some settings.

An excellent source of information on updated treatment guidelines is available at https://clinicalinfo.hiv.gov/en/guidelines. Healthcare professionals involved in the care of persons with HIV are urged to consult the most current literature on the principles and strategies for ART therapy.

Pharmacologic Therapy

Several methods of therapeutic intervention have been evaluated against HIV, including systemic antiretroviral drugs (the focus of this chapter) for direct inhibition of chronic viral replication or prevention of HIV acquisition; vaccination; immunomodulators to help stimulate and restore the immune system; and topical antiretroviral drugs or virucides (chemicals that destroy intact viruses) to prevent HIV infection. Antiretroviral medications are the only FDA-approved options for HIV treatment, and the latter three approaches are now investigational. Several approaches for an HIV vaccine are in development, including whole killed virus, subunit and peptide vaccination, recombinant live vector, naked DNA delivery, adenovirus vectors, and mRNA. Historically, vaccine progress has been slow. Genetic variability in HIV and a nascent understanding of the role of the immune system in suppressing viral replication are significant barriers to the development of an effective HIV vaccine with long-lasting and protective immunity. Efforts are underway to understand the correlates of protection from various studies to inform the vaccine field going forward.[52,53] Immunomodulators have also been investigated as a way to restore immune function (eg, aldesleukin) and to potentially cure HIV through “shock and kill” strategies (activate the immune system to bring HIV out of latency, then suppress its replication).[54] Topical virucidal or antiretroviral drug formulations for vaginal or rectal use to prevent sexual transmission of HIV are in various phases of development.[11] Collectively, these agents have demonstrated modest efficacy and are discussed in more depth in the PrEP section.

Antiretroviral Agents

Systemic delivery of antiretroviral agents for direct inhibition of viral replication has been the most successful strategy for both treatment and prophylaxis. Five general classes of drugs are available: entry inhibitors (fusion inhibitors, CD4 post-attachment inhibitors, gp120 attachment inhibitors, and chemokine receptor antagonists), nucleos(t)ide reverse transcriptase inhibitors (N(t)RTIs), non-nucleoside reverse transcriptase inhibitors (NNRTIs), integrase strand transfer inhibitors (InSTIs), and HIV PIs (Table 148-3).[38] Newer agents exhibit significant advantages over first-generation drugs in terms of pharmacokinetics, tolerability, safety, and efficacy. This section will highlight specific advantages of newer agents over first-generation drugs and will focus the discussion on agents used most often. Updated drug information is available in the DHHS guidelines including common adverse events and dosing recommendations for hepatic and renal insufficiency for all antiretroviral drugs.[38] There are other antiviral medications that exhibit modest, non-suppressive anti-HIV activity against HIV, such as the anti-herpes and anti-hepatitis B antivirals acyclovir, adefovir, entecavir, foscarnet, and interferon-alpha. These therapies should not be used as alternative options for HIV treatment but can be used in the setting of suppressive ART.

TABLE 148-3

Selected Pharmacologic Characteristics of Selected Antiretroviral Compounds for HIV Treatment

Drug	F (%)	$t_{1/2}$[a]	Adult Dosing Recommendation[b] (doses/day)	Plasma C_{max}/C_{min} (ng/mL or mcg/L)	Distinguishing Adverse Effects
Integrase inhibitors (InSTI)					
Bictegravir	?	17.3 hr	50 mg orally once daily	6,150/2,610	Diarrhea, nausea, headache, weight gain
Cabotegravir		41 hr	Oral lead-in: 30 mg orally once daily × 28 days	8,000/4,600	Headache, nausea, abnormal dreams, anxiety, insomnia, depressive disorders, hepatotoxicity
Cabotegravir LA	N/A	6-12 weeks (absorption-limited)	600 mg/3 mL IM × 1 (loading) 400 mg/2 mL IM every 4 weeks (continuation)	8,000/1,500 4,200/2,800	IM only: injection site reactions
Dolutegravir	?	14 hr	50 mg orally once daily *Or* 50 mg orally twice daily	3,670/1,110 4,150/2,120	Insomnia, headache, depression, and suicidal ideation (rare - usually patients with preexisting psychiatric conditions), weight gain, hepatotoxicity, hypersensitivity reactions including rash (can be severe)
Elvitegravir (coformulated with cobicistat)	?	13 hr	150 mg orally once daily	2,100/290	Diarrhea, nausea, depression and suicidal ideation (rare - usually patients with preexisting psychiatric conditions)
Raltegravir	?	9 hr	400 mg orally twice daily *Or* 1,200 mg orally once daily	2,171/68.5 7,575/51.6	Rash (can be severe), nausea, headache, diarrhea, pyrexia, creatine phosphokinase increases, weight gain, insomnia, depression, and suicidal ideation (rare - usually patients with preexisting psychiatric conditions)
Nucleoside (nucleotide) reverse transcriptase inhibitors (NRTIs)					
Abacavir	83	1.5/20 hr	300 mg orally twice daily *Or* 600 mg orally once daily	3,000/20 4,260[c]	Hypersensitivity (HLA-B*5701 test to predict); possible increased risk of MI with recent or current use but studies vary

Emtricitabine	93	10/39 hr	200 mg orally once daily	1,800/90	Rarely pigmentation on soles and palms in non-White populations
Lamivudine	86	5/22 hr	150 mg orally twice daily *Or* 300 mg orally once daily	1,400/370 2,410/110	Headache
Tenofovir alafenamide	?	35/150 (tenofovir component) hours	25 mg orally once daily *Or* 10 mg orally once daily (when coformulated with cobicistat)	30/10	Diarrhea, nausea, headache; increased lipids and weight gain vs TDF; less renal and bone toxicity vs TDF
Tenofovir disoproxil fumarate	25	17/150 (tenofovir component) hours	300 mg orally once daily	299/115	Renal dysfunction (proximal tubulopathy), bone demineralization
Zidovudine	85	2/7 hr	200 mg orally three times daily *Or* 300 mg orally twice daily	1,020/100 2,290/20	Anemia, neutropenia, myopathy
Nonnucleoside reverse transcriptase inhibitors (NNRTIs)					
Doravirine	64	15 hr	100 mg orally once daily	962/396	Nausea, dizziness, abnormal dreams
Efavirenz	43	48 hr	600 mg orally once daily	4,072/1,768	CNS disturbances, rash, serum transaminase elevations, hiperlipidemia, QT prolongation
Etravirine	?	41 hr	200 mg orally twice daily	736/161	Rash (including SJS), nausea, hypersensitivity reactions
Nevirapine	93	25 hr	200 mg orally twice daily[d] *or* 400 mg orally once daily	5,400/3,730 6,658/2,929	Potentially serious rash (including SJS) and symptomatic hepatotoxicity
Rilpivirine	?	50 hr	25 mg orally once daily	280/120	Rash, depression, insomnia, headache, hepatotoxicity, QT prolongation
Rilpivirine LA		13-28 weeks	900 mg/3 mL IM × 1 (loading)	139/37.2 116/82.2	IM only: injection site reactions

			600 mg/2 mL IM every 4 weeks (continuation)		
Protease inhibitors (PIs)					
Atazanavir	68	7 hr	400 mg orally once daily *Or* 300 mg orally once daily[e]	2,298/120 4,420/636	Unconjugated hyper bilirubinemia, cholelithiasis, nephrolithiasis, serum transaminase elevations
Darunavir	82	15 hr	800 mg orally once daily[e] *Or* 600 mg orally twice daily[e]	7,070/3,860	Hepatotoxicity, rash, metabolic side effects
Lopinavir[f]	?	5.5 hr	800 mg orally once daily *or* 400 mg orally twice daily	9,800/7,100	Hyperlipidemia, GI intolerance, metabolic side effects
Pharmacoenhancers					
Cobicistat	?	3-4 hr	150 mg orally once daily	990/30	SCr increases
Ritonavir	60	3-5 hr	100 mg orally once daily *Or* 100 mg orally twice daily		GI intolerance, hyperlipidemia
Fusion inhibitors					
Enfuvirtide	84	3.8 hr	90 mg/1 mL SQ twice daily	5,000/3,300	Injection-site reactions, rare hypersensitivity reactions
CCR5 antagonists					
Maraviroc	33	15 hr	300 mg orally twice daily	618/33.6	Hepatotoxicity, abdominal pain, cough, dizziness
CD4 post-attachment inhibitors					
Ibalizumab-uiyk	N/A	79 hr	2,000 mg IV loading dose, then 800 mg (every 2 weeks)	567,000/230	Diarrhea, dizziness, nausea, rash, infusion reactions

Gp120 attachment inhibitors					
Fostemsavir	27	11 hr	600 mg orally twice daily	1,770/478	Nausea; QTc prolongation; transaminase and transient bilirubin elevations; sleep disturbance, dizziness

C_{max}, maximum plasma concentration; C_{min}, minimum plasma concentration; *F*, bioavailability; IM, intramuscular; IV, intravenous; PO, by mouth; SQ, subcutaneous; $t_{1/2}$, elimination half-life; LA, long acting.

[a] NtRTIs: Plasma NtRTI $t_{1/2}$/intracellular (peripheral blood mononuclear cells) NtRTI-triphosphate $t_{1/2}$; plasma $t_{1/2}$ only for other classes.

[b] Dose adjustment may be required for treatment-experienced patients with resistance mutations, weight, renal or hepatic disease, and drug interactions.

[c] C_{min} concentration typically below the limit of quantification.

[d] Initial dose escalation recommended to minimize side effects.

[e] Must be boosted with low doses of ritonavir (100-200 mg).

[f] Available as coformulation 4:1 lopinavir to ritonavir.

Data from Reference [38] *and individual package inserts.*

Reverse transcriptase inhibitors consist of two classes: those that are chemical derivatives of purine- and pyrimidine-based nucleosides and nucleotides (nucleoside/nucleotide reverse transcriptase inhibitors [NRTIs]) and those that are not (nonnucleoside reverse transcriptase inhibitors [NNRTIs]). Recommended NRTIs include the thymidine analog zidovudine (AZT or ZDV); the deoxycytidine analogs emtricitabine (FTC) and lamivudine (3TC); the deoxyguanosine analog abacavir sulfate (ABC); and tenofovir, which is a deoxyadenosine-monophosphate nucleotide analog (a nucleotide is a nucleoside with one or more phosphates). **Note that drug abbreviations are provided here and below for reference, but their use is discouraged because they may lead to prescribing or administration errors.**

As a class, the NRTIs require phosphorylation in cells to the 5′-triphosphate moiety to become pharmacologically active. Intracellular phosphorylation occurs by cytoplasmic or mitochondrial kinases and phosphotransferases (not viral kinases). The 5′-triphosphate moiety acts in two ways: (1) it competes with endogenous deoxyribonucleotides for the catalytic site of reverse transcriptase, and (2) if taken up and incorporated by reverse transcriptase, it prematurely terminates DNA elongation, as it lacks the requisite 3′-hydroxyl for sugar-phosphate linking. NRTIs are active against both HIV-1 and HIV-2.[38] Emtricitabine, lamivudine, and tenofovir are also active against hepatitis B virus, and a combination of these agents should be used when possible in HIV–hepatitis B coinfected patients.

Tenofovir comes in two pro-drug formulations, tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). Tenofovir disoproxil fumarate is an ester pro-drug that releases tenofovir upon absorption and first pass metabolism, producing relatively high systemic concentrations of tenofovir, which confers some risk of proximal tubulopathy and bone demineralization (both usually mild and reversible). Tenofovir alafenamide contains a different pro-drug configuration such that more of the intact pro-drug reaches the systemic circulation and penetrates lymphoid cells. Once in lymphoid cells, tenofovir is released via hydrolysis by cathepsin A in lymphoid tissues or in hepatic cells via carboxylesterase 1. This strategy results in higher intracellular concentrations in cells of interest, but lower systemic tenofovir concentrations and less change in markers of proximal tubulopathy and bone demineralization.[55] However, TAF increased weight gain and lipid abnormalities in comparison to TDF.[56,57]

Although NRTI triphosphates (or diphosphate for tenofovir) are specific for HIV reverse transcriptase, their adverse effects may be caused in part by inhibition of mitochondrial DNA or RNA synthesis.[38] It is largely this problem that differentiates the first-generation drugs (didanosine, stavudine, and zidovudine) from the agents used most often (tenofovir disoproxil fumarate, tenofovir alafenamide, emtricitabine, lamivudine, and abacavir). The mitochondrial toxicities associated with first-generation drugs include peripheral neuropathy, pancreatitis, lipoatrophy (subcutaneous fat loss), myopathy, anemia, and rarely life-threatening lactic acidosis with fatty liver. The newer agents exhibit less potential to cause these toxicities, but they still have their own adverse event profiles to be considered (see Table 148-3).

Most of the newer NRTIs are eliminated by the kidney, and dose adjustments are required for renal insufficiency; abacavir is an exception as it is metabolized in the liver and should not be used in advanced hepatic impairment. Resistance has been reported for all NRTIs, including cross-resistance within the class as multiple and/or specific mutations in the viral genome accrue.[58]

NNRTIs are a chemically heterogeneous group of agents that bind noncompetitively to reverse transcriptase adjacent to the catalytic site, forcing a conformation change to the enzyme. Unlike NRTIs, NNRTIs do not require intracellular activation, do not compete against endogenous deoxyribonucleotides, and do not have intrinsic antiviral activity against HIV-2. Recommended NNRTIs include doravirine (DOR), efavirenz (EFV), etravirine (ETR), nevirapine (NVP), and rilpivirine (RPV).[38] As a class, the NNRTIs are generally associated with rash and hepatotoxicity, including rare life-threatening cases, particularly for nevirapine.[38] The use of first-generation NNRTIs (nevirapine and efavirenz) are on the decline largely because of tolerability and/or safety concerns. However, some patients have remained on efavirenz-based therapy and both efavirenz and nevirapine are still used in certain regions of the world. NNRTIs tend to have long plasma half-lives and they are mainly cleared by liver and/or gut-mediated metabolism through the cytochrome P450 (CYP) enzyme system. Rilpivirine is the only NNRTI available in both an immediate release oral and a long-acting injectable formulation. Caution should be used for those with advanced hepatic insufficiency (nevirapine should not be used in moderate or advanced hepatic insufficiency). NNRTIs can be perpetrators of drug-drug interactions, most often induction of CYP metabolism. Exceptions to this are doravirine and rilpivirine, which do not induce or inhibit CYP metabolism. The older NNRTIs were unique in that a single mutation was needed to confer high-level cross-resistance for the class (not including etravirine and doravirine). This has been termed a *low-genetic barrier* to resistance.[58]

Recommended HIV PIs include atazanavir (ATV), darunavir (DRV), and lopinavir (LPV). Ritonavir (RTV) is also an older PI that is now used as a pharmacoenhancer for this class of drugs. HIV PIs competitively inhibit the cleavage of the gag-pol polyprotein, which is a crucial step in the viral maturation process, thereby resulting in the production of immature, noninfectious virions. HIV PIs have activity against HIV-1 and HIV-2 (particularly darunavir and lopinavir).[38] HIV PIs are generally associated with GI distress and metabolic changes, such as increased lipids, insulin insensitivity, and changes in body fat distribution. Some of these issues can be traced to formulation problems due to limited aqueous solubility, requiring high levels of excipients and large pill burdens. The first-generation HIV PIs (eg, indinavir, nelfinavir, saquinavir, lopinavir) exhibited poor solubility leading to erratic absorption (nelfinavir, saquinavir), crystallization of drug in urine (indinavir), gastrointestinal distress (nelfinavir, lopinavir), and hyperlipidemia (lopinavir). Generally, the newer HIV PIs, darunavir and atazanavir, improve upon, but do not eliminate, these issues. HIV PIs are cleared by liver- and gut-mediated metabolism (mainly CYP3A), and dose adjustments may be required in hepatic insufficiency. HIV PIs are almost always used with low doses of CYP3A inhibitors, ritonavir or cobicistat, to increase the plasma concentrations of the HIV PI of interest. Thus, CYP3A- and P-gp-mediated drug interactions with concomitant medications are important considerations for PIs. Resistance to the HIV PIs generally requires the buildup of multiple mutations, termed a *high-genetic barrier* to resistance. Multiple mutations can lead to cross-resistance.[58]

There are four drugs that block HIV entry and these are generally reserved for treatment-experienced patients. Enfuvirtide (T20) is a synthetic 36-amino-acid peptide that binds gp41, inhibiting envelope fusion of HIV-1 with the target cell. It does not have activity against HIV-2. Subcutaneous injection is the preferred route of administration and injection-site reactions (pain, erythema, nodules) are the most common adverse effects, nearing 100% incidence. Enfuvirtide is cleared via protein catabolism and amino acid recycling.[38] Maraviroc is a CCR5 antagonist with activity against HIV-1 and HIV-2. The long-term consequences of blocking CCR5 (a human receptor) are unknown but may include increased susceptibility to disease by flaviviruses (eg, West Nile virus and tickborne encephalitis virus).[59] One advantage of targeting a human receptor is that resistance to CCR5 antagonists may be more difficult to develop. Because CCR5 antagonists are only effective against R5 virus and not X4 virus, a viral tropism assay must be performed prior to using a CCR5 antagonist. Maraviroc is a CYP3A and P-glycoprotein substrate and is therefore susceptible to drug-drug interactions and caution should be used in those with advanced hepatic insufficiency. Maraviroc has been associated with rash and hepatotoxicity. Resistance mutations have been identified for enfuvirtide, which has a low-genetic barrier to resistance, but assays for maraviroc resistance have not been developed other than the R5 versus X4 tropism test.[38,58] Ibalizumab-uiyk is a recombinant humanized monoclonal antibody with activity against HIV-1 that binds to domain 2 of the CD4 receptor on host cells. The binding of ibalizumab-uiyk to the CD4 receptor does not affect its ability to bind gp120 on viral particles, but it interferes with the post-attachment steps necessary for the entry of HIV-1 into host cells. Ibalizumab-uiyk is administered by infusion and is indicated for heavily treatment-experienced adults with multidrug-resistant HIV-1 infection who are failing their current antiretroviral regimen.[60] It has activity against R5-tropic, X4-tropic, and dual-tropic viruses. The most common adverse effects associated with ibalizumab-uiyk include diarrhea, dizziness, nausea, and rash. Decreased susceptibility to ibalizumab-uiyk has been seen in some subjects, but the clinical significance of this is not well understood. There is no evidence of cross-resistance between ibalizumab-uiyk and any other antiretroviral class. Fostemsavir is an oral prodrug of temsavir, which is an attachment inhibitor that binds near the CD4 receptor binding site to prevent conformational changes in gp120, thus preventing HIV from entering CD4 cells.[61] This medication is indicated as salvage therapy in heavily treatment-experienced patients. Temsavir is metabolized by esterases and CYP3A4 and is susceptible to drug-drug interactions with CYP3A4 inducers. Temsavir caused QTc prolongation at doses multiple-fold higher than those used clinically. Caution is advised in patients with a history of QTc prolongation or associated cardiac diseases, or in combination with other medications that may cause Torsades de Pointes.

InSTIs include bictegravir (BIC), cabotegravir (CAB), dolutegravir (DTG), elvitegravir (EVG), and raltegravir (RAL). Cabotegravir is the only InSTI available in both immediate release oral and long acting injectable forms. InSTIs bind to HIV integrase while it is in a specific complex with viral DNA and inhibit the strand transfer that incorporates the proviral DNA into the chromosomal DNA. InSTIs are active against HIV-1 and HIV-2. Cabotegravir, dolutegravir, and raltegravir are primarily glucuronidated by UGT1A1 and are not susceptible to major CYP-mediated drug interactions, although other kinds of interactions are important (Table 148-2). In particular, polyvalent cation containing antacids and mineral supplements bind InSTIs in the gut leading to reduced bioavailability. Recommendations vary on how to mitigate these interactions, including temporal separation (eg, elvitegravir and raltegravir), simultaneous administration with food (eg, bictegravir and dolutegravir), or consideration of an antacid with a different mechanism of action (eg, histamine receptor antagonists or proton pump inhibitors). Bictegravir is metabolized by both UGT1A1 and CYP3A4 and is susceptible to interactions through both enzymatic pathways. Elvitegravir is extensively metabolized by CYP3A and is coformulated with cobicistat, a potent CYP3A inhibitor, to optimize drug exposure and enable once-daily dosing. InSTIs are relatively well-tolerated with adverse events that include rash, nausea, and headache. This class of medications, particularly dolutegravir, has also been associated with CNS and psychiatric side effects (eg, insomnia, depression, and increased risk of suicidality) with a higher risk among those with a history of psychiatric conditions. InSTIs may also cause more weight gain than PIs or NNRTIs, with the greatest weight gain with bictegravir and dolutegravir.[62,63] InSTIs should be used with caution in advanced hepatic insufficiency. Multiple mutations have been identified conferring resistance to InSTIs, including cross-resistance as mutations accrue. Bictegravir and dolutegravir have a higher genetic barrier to resistance compared with elvitegravir and raltegravir.[58]

Novel antiviral agents in the classes listed above and agents in new drug classes that exploit other steps in the HIV life cycle (see Fig. 148-1) are in development, with a focus on long-lasting activity and/or high activity against drug-resistant virus.[64] Capsid inhibitors are a novel drug class in development, with the potential to interfere with multiple different steps in the HIV replication cycle. The capsid inhibitor lenacapavir is being evaluated in long-acting formulations of up to six months duration for both HIV treatment and prevention. Islatravir is a potent nucleoside analog reverse transcriptase/translocation inhibitor (translocation is the repositioning of reverse transcriptase after incorporating a nucleotide so it is ready to accept the next incoming nucleotide). Islatravir is being studied in long-acting formulations for up to six months duration as well. Long-acting antiretroviral therapy is emerging as a new treatment paradigm.

Drug Interactions

⑥ Medical use of antiretroviral agents is complicated by clinically significant drug-drug interactions that can occur with many of these agents.[38,65] Some interactions are beneficial and used purposely (eg, ritonavir and cobicistat as pharmacokinetic enhancers); others may be harmful, leading to dangerously elevated (eg, toxic) or inadequate drug concentrations (non-suppressive). Clinicians involved in the pharmacotherapy of HIV must understand the mechanistic basis for these interactions and maintain a current knowledge of drug interactions for these reasons.

Antiretroviral-associated drug interactions encompass a variety of mechanisms, including but not limited to: CYP3A-associated first-pass metabolism, efflux and uptake drug transporters, and systemic clearance. The newer HIV PIs, NNRTIs (doravirine, etravirine, and rilpivirine), the CCR5 antagonist maraviroc, and the InSTI elvitegravir are extensively metabolized by CYP3A. In general, efavirenz, etravirine, and nevirapine are inducers of CYP3A, whereas the PIs and their pharmacoenhancers inhibit CYP3A. Ritonavir is a potent mechanism-based inhibitor of CYP3A-mediated metabolism and is now used exclusively at lower doses as a pharmacokinetic enhancer of other HIV PIs. Similarly, cobicistat, which is an analog of ritonavir without antiretroviral activity, is also a potent mechanism-based inhibitor of CYP3A activity and is used in a similar fashion. However, the interaction profiles for ritonavir and cobicistat differ and thus when switching between these agents similar interactions cannot be assumed.[66] PIs and pharmacoenhancers also inhibit efflux (eg, P-glycoprotein and breast cancer resistance protein [BCRP]) and uptake transporters (eg, organic anion transporting polypeptide [OATP]), which contributes to the overall drug-drug interaction profile including certain statins (eg, rosuvastatin)[67] and the direct oral anticoagulant, dabigatran etexilate.[68] Some PIs including ritonavir induce transporters, making drug-drug interactions difficult to predict.

Darunavir and lopinavir must be taken with ritonavir or cobicistat to achieve optimal plasma concentrations. Atazanavir is also primarily used with ritonavir or cobicistat for the same reason, though it can be used without a pharmacoenhancer if dose adjusted. Many potential concomitant drugs on the market are substrates for CYP3A and drug transporters, and are therefore susceptible to clinically relevant drug interactions with HIV PIs, NNRTIs, and pharmacoenhancers. Agents with narrow therapeutic indices and/or that exhibit major changes in pharmacokinetics with inhibitors or inducers of enzymes and/or transporters for which they are substrates are most important in this regard. Examples include, but are not limited to simvastatin, lovastatin, corticosteroids (including inhaled, intranasal, and intraarticular), ergot derivatives, some antiarrhythmics, some erectile dysfunction drugs, some anticoagulants, and some anti-cancer agents.

The drug interaction potential of antimycobacterium agents, specifically the rifamycins, are particularly relevant, given the high potential for such infections in persons with HIV.[65] Rifampin and rifapentine, potent inducers of CYP3A metabolism and conjugation enzymes, are contraindicated with the use of HIV PIs, most NNRTIs, bictegravir, cabotegravir (oral and injectable), elvitegravir, and maraviroc because antiretroviral concentrations are reduced substantially even with ritonavir enhancement. Efavirenz should be administered as a 600 mg dose with rifampin; the 400 mg dose should not be used.[38] The usual dose of efavirenz can be used with rifapentine; dose adjustment is not required, which may be due in part to the concomitant use of isoniazid.[69] Raltegravir and dolutegravir doses should be increased in the presence of rifampin, with raltegravir dosing doubled and dolutegravir being administered twice daily. Dolutegravir and raltegravir do not require dose adjustment with once-weekly rifapentine, but should not be coadministered if rifapentine is administered once daily. The use of tenofovir alafenamide, a P-gp substrate, with rifamycins is also discouraged unless benefits outweigh risks and virologic response is closely monitored.[38,70,71] Tenofovir disoproxil fumarate does not require dose adjustment and may be a suitable alternative in these cases. Ritonavir enhancement generally allows coadministration of HIV PIs with rifabutin.[38,65] In such cases, the rifabutin dose will require adjustment, given its CYP3A-mediated clearance. Similarly, the herbal product St. John's wort (*Hypericum perforatum*) is a potent inducer of metabolism and is contraindicated with PIs, NNRTIs, INSTIs, tenofovir alafenamide, and maraviroc.[38] The pharmacology of CYP3A interactions may be complicated by simultaneous induction/inhibition of drug transporter–mediated (eg, P-glycoprotein) bioavailability or clearance and/or other phase I (eg, CYP 2B6 for RTV) or phase II enzymes.

Some antiretroviral drugs require acidic environments for optimal absorption leading to interactions with antacids, particularly proton-pump inhibitors (eg, atazanavir, rilpivirine). On the other hand, some antiretroviral agents chelate polyvalent cations in antacids or mineral supplements, reducing absorption following co-administration (eg, InSTIs). Other potential mechanisms for drug interactions include inhibition of renal tubule secretion (eg, tenofovir and OAT inhibitors; inhibition of MATE and/or OCT2 by dolutegravir, bictegravir, and cobicistat), and antagonistic phosphorylation for NRTIs of the same nucleobase (eg, lamivudine and emtricitabine). This list of drug interactions and mechanisms for drug interactions is not complete. Clinicians who treat HIV must monitor for, and stay abreast of, antiretroviral drug interaction data. Websites are available that catalog and regularly update HIV drug-interaction information (http://www.hiv-druginteractions.org/), and the DHHS guidelines for antiretroviral use provide, and regularly update, excellent summaries of known clinically relevant drug interactions.[38]

Landmarks in the Evolution of Antiretroviral Therapy

⑦ ART has undergone major changes over the past decades. Illustrating these changes is important for a thorough understanding of current treatment strategies. The first landmark in this evolution was the availability of zidovudine, the first antiretroviral agent, which conferred a survival benefit in persons with AIDS, when given as monotherapy. A combination of two NRTIs was superior to zidovudine monotherapy in immunologic and virologic parameters, as well as survival benefit. Later, triple therapy (two NRTIs with an HIV PI or NNRTI) was associated with reduced incidence of OIs and improved survival, establishing the current paradigm of ART. Triple drug therapy has since evolved to include new drug classes (eg, INSTI), coformulations, and better tolerated agents. This has in turn led to improvements in convenience, tolerability, safety, and virologic efficacy—enabling two drug therapy in some circumstances.

⑦ Taken together, these landmarks established that HIV should not be treated with single or dual NRTIs alone. Recommendations for initial treatment of most people with HIV now advocate a minimum of two active antiretroviral agents provided at least one in the regimen has a high barrier to resistance (eg, dolutegravir or boosted darunavir). Recommended initial regimens for most people with HIV comprise an InSTI with 1 to 2 NRTIs, and include bictegravir with tenofovir alafenamide plus emtricitabine; dolutegravir with tenofovir (as either tenofovir disoproxil fumarate or tenofovir alafenamide) plus emtricitabine; dolutegravir plus abacavir/lamivudine (abacavir can only be used in patients who are HLA-B*5701 negative); and dolutegravir with lamivudine (except in persons with baseline HIV viral loads >500,000 copies/mL (500×10^6/L), hepatitis B coinfection, or when antiretroviral therapy is to be initiated prior to the availability of hepatitis B serologic testing or HIV genotypic resistance testing). Multiple alternative regimens are also safe and effective, but have some disadvantages compared with those recommended for most persons with HIV such as dosing convenience (eg, the use of multiple tablets or twice daily administration), drug-drug interactions, weaker virologic responses with high viral loads, lower tolerability, or greater risk of long-term toxicities. Recommended antiretroviral regimens for initial therapy are listed in Table 148-2.

Recommended first-line ART regimens constantly evolve and clinical controversies may emerge as data and clinical experience accrue and new strategies come under consideration, thus it is always advised to review the DHHS guidelines for the most updated ART recommendations.

Adherence

The simplest definition of adherence is the patient's follow-through on taking medication as directed. As with any chronic therapy, variable adherence to ART is common, and significantly impacts virologic response. Factors associated with poor adherence include major psychiatric illnesses, active substance use, unstable social circumstances, adverse events, and poor adherence with clinic visits.[38] Most, but not all, modern ART regimens consist of coformulations and long half-life drugs allowing for once-daily dosing (sometimes without food restrictions), which facilitates improved adherence compared with multiple dose units, multiple doses per day, and food restrictions with dosing. Average adherence rates are approximately 80% with antiretroviral regimens. Longer dosing "holidays" increase the risk of breakthrough viremia; however, newer regimens aremore forgiving.[72] As clinicians, it is critical to establish a relationship of trust with the patient and to communicate to the patient the importance of proper medication taking. Education should be aimed at understanding the disease process, monitoring, goals of therapy, and consequences of poor adherence. An individual's "readiness" to take medications should be clearly established before treatment is initiated.[38] Help from caregivers, friends, and/or family members should be leveraged by the patient because social and psychological support are among the most important factors that influence adherence in this patient population. Strategies to encourage adherence, such as pill boxes, alarms, and setting a routine schedule should be discussed. Pharmacological approaches are among strategies being used to assess adherence objectively.[73]

Efficacy

Based on clinical trial data, more than 90% of patients will achieve undetectable viral loads with preferred and alternative ART regimens.[74–76] Given high efficacy across modern ART regimens, side effect profiles can help distinguish preferred versus alternative regimens. Starting with the nucleos(t)ide analog backbones, several studies have compared tenofovir alafenamide against tenofovir disoproxil fumarate, which have generally shown similar efficacy rates. Tenofovir disoproxil fumarate is associated with greater renal toxicity and bone demineralization, especially with the concomitant use of pharmacoenhancers,[77] whereas tenofovir alafenamide has been associated greater weight gain and lipid increases.[56] Abacavir–lamivudine combined with dolutegravir exhibits superior efficacy rates regardless of baseline viral load compared with efavirenz–tenofovir disoproxil fumarate–emtricitabine,[76] and similar efficacy rates to other InSTI combinations recommended for most people with HIV.[75] Together, these studies established recommendations for tenofovir disoproxil fumarate– emtricitabine or lamivudine, tenofovir alafenamide–emtricitabine, or abacavir–lamivudine as initial NRTI components of therapy. As mentioned above, if abacavir is to be used in any regimen, a test for the presence of HLA-B*5701 must be done as its presence has been strongly correlated with the development of abacavir hypersensitivity. Should this test be positive, an abacavir allergy should be added to the patient's medical record and abacavir should not be used in the patient, as the hypersensitivity reaction can be life-threatening.

The third active agent of ART regimens has also evolved based on large, randomized, controlled trials. Efavirenz and PIs maintained a long history as the recommended third active agent until comparative trials demonstrated poorer tolerability and more therapy discontinuations for efavirenz and PIs versus InSTIs.[76,78] Together, these and other studies support recommendations for InSTIs as third active agents for initial ART in most people with HIV. Many agents are available for inclusion in regimens recommended in certain clinical situations, including NNRTIs (eg, doravirine, efavirenz, or rilpivirine) or PIs (darunavir and atazanavir boosted with either cobicistat or ritonavir).[38] Dual ART therapy may also be considered in situations where the use of tenofovir disoproxil fumarate, tenofovir alafenamide, or abacavir are not optimal choices. Dual ART regimens for initial therapy include more potent agents (dolutegravir plus lamivudine[79] and darunavir/ritonavir plus either lamivudine or raltegravir) and have evidence supporting their use in patients who are not ideal candidates for other recommended ART regimens. Clinicians are urged to consult the most recommended preferred and alternative regimens, as they are continuously updated with new studies and as longer-term follow-up data accrue.

Regimen Simplification and Long-Acting Therapies

Patients with sustained undetectable HIV-RNA taking out-of-date drug regimens may be candidates for simplification to one of the recommended regimens as previously described, or a more desirable alternative regimen based on past treatment history and other patient-specific factors. There are two additional dual antiretroviral combinations that may be considered in participants who are suppressed: dolutegravir with rilpivirine,[80] and long-acting intramuscular injectable cabotegravir with rilpivirine. As these drugs do not have activity against hepatitis B, they should be avoided in persons with HIV and hepatitis B coinfection. Screening for drug-drug interactions and avoiding use in individuals with resistance mutations to individual drug components is also critical to avoid therapeutic failure. Dolutegravir with rilpivirine is available as a coformulated tablet, and this regimen has shown high rates of continued virologic suppression following ART switch.

Cabotegravir with rilpivirine represents the first long-acting injectable combination approved for this indication. Studies with intramuscular cabotegravir/rilpivirine demonstrated noninferiority to oral ART.[81] This combination is only recommended in persons with HIV who have been suppressed and on stable ART for at least 3 to 6 months.[38] Cabotegravir with rilpivirine also cannot be used in pregnant or breastfeeding women until additional data supporting its use are available in this population. An oral lead-in period for 28 days is recommended to ensure tolerability before starting the injections. The first intramuscular injection of cabotegravir with rilpivirine is given as a loading dose on the last day of oral therapy (600 mg [3 mL] of cabotegravir and 900 mg [3 mL] of rilpivirine), and then is administered as a maintenance dose (400 mg [2 mL] of cabotegravir and 600 mg [2 mL] of rilpivirine) once-monthly thereafter. Injections are administered intramuscularly into the gluteal muscle. Regulatory authorities are evaluating whether the dosing frequency can be extended to every two months in persons with HIV. A window period of 7 days is allowed around scheduled doses for unforeseen circumstances, but gaps beyond 7 days may require bridging with oral therapy to ensure that subtherapeutic exposures do not occur. The most common side effects are mild-moderate injection site reactions (>80%) that generally decrease over time. Despite the high rates of injection site reactions, over 90% of participants in clinical trials still preferred long-acting injectable options over daily oral ART. Other long-acting therapies in development such as lenacapavir and islatravir hold great promise to further expand options for people living with HIV.[64]

Resistance

⑨ Regimen failure may be associated with antiretroviral resistance, and testing for such resistance is a useful clinical tool.[38,58] The two types of resistance tests available are phenotype and genotype. A phenotype test determines the concentration of antiretroviral agent necessary to inhibit replication of the patient's viral isolate by 50% (inhibitory concentration of 50% [IC_{50}]) in a recombinant in vitro viral assay. Results usually are expressed as a fold change in susceptibility (IC_{50}) compared with a wild-type laboratory strain virus. Generally, the fold-change in IC_{50} increases as HIV accumulates additional mutations that confer resistance to a particular drug. However, a single mutation may confer a high fold-change in IC_{50} for some drugs (eg, lamivudine, emtricitabine, efavirenz, nevirapine), rendering them ineffective after a single mutation. Although small-to-moderate increases in the fold change suggest reduced susceptibility to that antiretroviral agent, resistance may not be absolute, and partial susceptibility may remain. Theoretically, drug concentrations may be increased to overcome reduced susceptibility. The strength of phenotypic testing is to provide resistance information for complex mutation patterns, but it is also associated with higher cost, limited number of commercial providers, and slower turnaround time for results. Genotyping assesses genetic mutations and associated codon changes in gp41, reverse transcriptase, integrase, or protease in the patient's virus and compares it with the wild-type sequence. Certain mutations are known to confer resistance to specific drugs. An updated list of drug resistance mutations can be found at https://www.iasusa.org/resources/hiv-drug-resistance-mutations/, and the Stanford HIVdb Program also has useful tools for analyzing HIV drug resistance mutations: https://hivdb.stanford.edu/. Mutations are listed by the wild-type amino acid followed by the position in the protein or enzyme and end with the mutation found in the patient's virus. For example, a common mutation caused by lamivudine and emtricitabine is the M184V mutation: a substitution of valine (V) for methionine (M) at the 184 position of reverse transcriptase. Mutations can confer varying degrees of antiretroviral drug resistance and in some cases, weighting algorithms have been developed to predict the relative impact of mutation combinations on antiretroviral activity. Algorithms have also been developed to predict a phenotype from a genotype test (ie, virtual phenotype). Resistance mutations may not be purely detrimental, for example, while M184V confers significant resistance to lamivudine and emtricitabine, it is also associated with a less fit virus. Interpretation of genotype resistance tests is complex; the reader is encouraged to obtain expert advice and consult the most recent guidelines on HIV resistance testing.

Treatment of Special Populations

Pregnancy

Several considerations are relevant to the treatment of pregnant persons, including the health of the mother, prevention of HIV transmission to the fetus, potential for teratogenicity, and drug dosing issues based on pharmacokinetic changes during pregnancy. Treatment recommendations should be consulted to address the specific requirements for pregnant people with HIV and the prevention of vertical transmission.[19] Generally, pregnant people should be treated as would nonpregnant people, with the goal of maximally suppressing HIV-RNA. Pregnant people already on a suppressive regimen may remain on their current therapy unless there are known safety or efficacy concerns with the combination that they are taking. Preferred initial regimens for HIV treatment during pregnancy include a dual NRTI backbone (abacavir/lamivudine or tenofovir disoproxil fumarate/emtricitabine or lamivudine) with either an InSTI (dolutegravir or raltegravir) or boosted PI (atazanavir/ritonavir or darunavir/ritonavir). Alternative options include tenofovir alafenamide/emtricitabine or zidovudine/lamivudine for a dual NRTI backbone, and efavirenz or rilpivirine with one of the recommended NRTI backbones.

Efavirenz was historically avoided in persons planning to become pregnant due to concerns of neural tube defects, but a large-scale clinical study and ongoing monitoring of the Antiretroviral Pregnancy Registry (http://www.apregistry.com/HCP.aspx) have since shown no increased risk of birth defects with efavirenz in comparison to other ART options or background rates in pregnant people without HIV. Dolutegravir use at the time of conception was also associated with a higher rate of neural tube defects in infants in a preliminary analysis from the Tsepamo study. Long-term follow-up with additional women showed lower rates and the difference was no longer statistically significant, and other studies have not shown a signal.[19] Nonetheless, the potential risks and known benefits of dolutegravir treatment should be discussed with people of child-bearing potential. Cobicistat-containing regimens should be avoided in pregnancy as exposures to cobicistat and co-formulated medications (ie, atazanavir, darunavir, and elvitegravir) are significantly reduced during pregnancy, which may increase the risk of treatment failure and perinatal HIV transmission.[19,82] If a person becomes pregnant while on one of these regimens, consideration should be given toward switching therapy, which may also carry its own risk of breakthrough, or more frequent viral load monitoring may be performed. Infants born to people with HIV require prophylaxis to prevent HIV transmission, and the exact recommendations vary depending on the maternal viral load, treatment history, and level of risk for transmission. Zidovudine is recommended intrapartum depending on the mother’s viral load (more than 1,000 copies/mL [1×10^6/L] or unknown), based on early studies demonstrating clear prophylactic effectiveness as well as extensive familiarity with the side effect profile.[19] Infants considered low risk for perinatal HIV transmission (ie, maternal viral load suppressed at delivery and no adherence concerns) should receive zidovudine prophylaxis for 4 weeks after birth. Infants considered high risk (ie, mother received either no antepartum or intrapartum ART, only intrapartum ART, or antepartum ART but did not achieve viral suppression) should receive presumptive HIV treatment with zidovudine/lamivudine and either nevirapine or raltegravir from birth through 6 weeks of age. Perinatal HIV transmission has been reduced to less than 0.5% for pregnant people who are treated with ART and when infant prophylaxis is used. Breastfeeding is not recommended in the United States, but in resource-limited settings where lack of clean water makes breastfeeding a more favorable option, infants should receive additional prophylaxis.[49]

Preventing HIV Transmission

HIV treatment is a necessary component of reducing HIV-associated morbidity and mortality. However, it is also critical for preventing new HIV transmissions from occurring. There are several approaches for preventing new HIV transmissions as detailed in this section. Pharmacists play an important role in both treating and preventing HIV, and some states now allow pharmacists to prescribe and dispense HIV pre- and postexposure prophylaxis (PEP) in recognition of the critical role that pharmacists play in this cascade.

Undetectable Equals Untransmittable (U=U)

Undetectable equals untransmittable (“U=U”, or Treatment as Prevention [TasP]) refers to the concept that people with HIV who achieve and maintain suppressed or undetectable viral loads (meaning viral loads <200 copies/mL [200 x 10^3/L)) do not sexually transmit HIV to others.[6] This was demonstrated through multiple clinical studies that evaluated serodiscordant (ie, one partner with HIV and one without HIV) heterosexual and male-male couples. No linked HIV transmissions occurred between couples when the partner with HIV maintained a suppressed viral load. U=U requires persons with HIV to remain adherent to their prescribed ART and thus maintain suppression (exact length varies by duration of therapy and confirmation of viral suppression).[38,83] Individuals should be counseled on the need to remain adherent with routine viral load monitoring if solely following the U=U strategy and should still undergo routine STI screening. Partners without HIV should still be offered PrEP, particularly if unsure whether their partner’s viral load is undetectable, if they have multiple sexual partners, or if they feel more comfortable taking PrEP. PEP should also be offered in cases where the partner with HIV has been inconsistently taking ART or is no longer suppressed. Condom use can help prevent other STIs. U=U does not cover other routes of HIV transmission, such as breastfeeding, sharing of drug injection equipment, or needlestick injuries.

Post-Exposure Prophylaxis (PEP)

Protection of people from potential HIV exposure is an important concern. The CDC has issued guidelines governing antiretroviral PEP of occupational (oPEP) and other non-occupational HIV exposures (nPEP) that should be consulted for updates as the knowledge in this field evolves.[13,16] Occupational exposures are those that happen in a work setting, most commonly needlestick injuries in healthcare workers, whereas nonoccupational exposures occur outside of work, such as condomless intercourse or injection drug use. The principles are to assess the exposure risk and treat as soon as possible after high-risk exposures to prevent HIV infection. Assessing the exposure risk requires knowledge of the HIV-infection status of the source individual, which may be difficult to ascertain. The HIV status of the source should be determined as soon as possible with a rapid HIV test, whenever feasible. However, providers may have to rely on reasonable suspicion when this is not possible, so provider expertise is essential. PEP should not be delayed while waiting on the HIV status of the source if reasonable suspicion is present. PEP should be considered an urgent medical situation. The guidelines as of October 2021 recommend conventional ART regimens as summarized in Table 148-4, initiated as soon as possible and within a maximum of 72 hours of the potential exposure. Animal studies show reduced PEP efficacy when initiated 72 hours or more after the exposure.[16] The optimal duration of treatment is unknown, but at least 4 weeks of therapy is advocated. Expert consultation is needed when exposure to drug-resistant virus is suspected or confirmed to optimize the PEP regimen, but this should not delay initial initiation of PEP.

TABLE 148-4

Recommended Regimens for Occupational and Non-occupational Postexposure prophylaxis

Population	Ranking	Regimen
Occupational post-exposure prophylaxis (oPEP)[16]		
Healthcare workers	Preferred	Tenofovir disoproxil fumarate 300 mg/emtricitabine 200 mg once daily + raltegravir 400 mg twice daily
	Alternative	Consult guidelines
Non-occupational post-exposure prophylaxis (nPEP)[13]		
Adults and adolescents ≥13 years, including pregnant persons, and normal renal function (CrCl ≥60 mL/min [1.0 mL/s])	Preferred	Tenofovir disoproxil fumarate 300 mg/emtricitabine 200 mg once daily + raltegravir 400 mg twice daily or dolutegravir 50 mg once daily
	Alternative	Tenofovir disoproxil fumarate 300 mg/emtricitabine 200 mg once daily + darunavir 800 mg/ritonavir 100 mg once daily
Adults and adolescents ≥13 years, including pregnant persons, and renal dysfunction (CrCl <60 mL/min [1.0 mL/s])	Preferred	Zidovudine/lamivudine (dose-adjusted per CrCl) + raltegravir 400 mg twice daily or dolutegravir 50 mg once daily
	Alternative	Zidovudine/lamivudine (dose-adjusted per CrCl) + darunavir 800 mg/ritonavir 100 mg once daily

Preexposure Prophylaxis (PrEP)

Preexposure prophylaxis (PrEP) involves the use of antiretroviral medications to prevent HIV. There are now three FDA-approved options for use in persons without HIV and at risk of HIV acquisition, to prevent infection should an HIV-exposure occur. These include oral emtricitabine with tenofovir (either in the form of tenofovir disoproxil fumarate or tenofovir alafenamide) and long-acting injectable cabotegravir. PrEP is effective in MSM, sero-discordant couples, and heterosexual men and women, including those who inject drugs, though the exact PrEP combinations that are approved in each of these population varies based on available data (see Table 148-5).[36,84]

TABLE 148-5

Recommended Regimens for Preexposure Prophylaxis

PrEP Option	**Emtricitabine with Tenofovir Disoproxil Fumarate**	**Emtricitabine with Tenofovir Alafenamide**	**Cabotegravir**
Initial FDA approval	2012	2019	2021
Administration route	Oral	Oral	IM injection
Indication	Adults and adolescents weighing at least 35 kg (77 lb)		
	Persons at risk through sex or injection drug use[a]	Persons at risk through sex, excluding people at risk through receptive vaginal sex	Persons at-risk through sex
Dosing	1 emtricitabine 200 mg/tenofovir disoproxil fumarate 300 mg tablet	1 emtricitabine 200 mg/enofovir alafenamide fumarate 25 mg tablet	Oral: 30 mg IM injection: 600 mg (3 mL)
	On-demand strategy also possible (“2-1-1”)[a]	On-demand strategy not recommended (no data)	On-demand strategy not recommended (no data)
Dosing frequency	Once daily	Once daily	Oral lead-in: once daily IM injection: once monthly × first 2 months then every 2 months thereafter
HIV monitoring[b]	Every 3 months	Every 3 months	Month 1 visit and every 2 months thereafter
Safety monitoring	Renal[c]	Renal[d], lipids	None
	Optional: bone density	Optional: bone density	
Side effects	“Start-up syndrome” during 1st month; headache, abdominal pain, weight loss	“Start-up syndrome” during 1st month; diarrhea, weight gain	Injection site reactions, headache, fever, fatigue, myalgia, rash
Use in renal impairment	CrCl ≥60 mL/min (1.0 mL/s)	CrCl ≥30 mL/min (0.5 mL/s)	Can be used; no restrictions

[a] Only TDF has been studied in persons who inject drugs, but this population is expected to benefit from all systemic PrEP forms.

[b] Only MSM: 2 pills 2-24 hours before sex (closer to 24 hours preferred), 1 pill 24 hours after first dose, 1 pill 48 hours after first dose. If sex occurs the day after completing the 2-1-1 series, continue taking 1 pill daily until 48 hours after the last sexual event. If sex occurs <7 days from the last 2-1-1 dose, resume 1 pill daily. If sex occurs ≥7 days between the last pill and next sexual event, reinitiate with 2 pills.

[c] Consists of laboratory testing (antigen, antibody, and HIV-1 RNA [PCR]) and assess signs/symptoms of acute HIV infection.

[d] Renal function should be assessed every 6 months for persons ≥50 years of age or with CrCl <90 mL/min (1.5 mL/s) and every 12 months in all other patients.

Data from References[36,103].

All sexually active adults and adolescents should be informed about PrEP. Prior to initiating PrEP, a negative HIV test should be documented, including negative symptoms of acute HIV infection. Reports of drug resistance from oral PrEP failures were mostly among individuals who initiated PrEP during acute HIV infection, in the window period before the rapid HIV test could detect infection. HIV acquisition during PrEP (especially for cabotegravir) can be challenging to diagnose because of prolonged HIV suppression and delayed antibody expression. HIV testing should be repeated at least every 3 months for those on oral PrEP, and for persons on cabotegravir, HIV testing is recommended at the month 1 visit (second injection) and then every two months thereafter (beginning with the third injection). Promotion of adherence and screening for potential drug-drug interactions is critical for PrEP effectiveness. It is also critical to continue routinely screening for STIs (all persons on PrEP) and hepatitis C virus (MSM, transgender women, and persons who inject drugs) as PrEP does not protect against these infections.

The most up-to-date PrEP guidelines should be consulted, as new PrEP strategies are under evaluation. Topical virucidal or antiretroviral drug formulations for use vaginally or rectally to prevent sexual transmission of HIV are in various phases of development. Use of a dapivirine ring resulted in a ~30% reduction in HIV acquisition, leading to review by the European Medicines Agency (EMA) for HIV prevention in women.[11]

EVALUATION OF THERAPEUTIC OUTCOMES

Two laboratory tests are used to evaluate response to ART: the plasma HIV-RNA and CD4 cell counts.[38] These tests should be performed at baseline, along with a medical history and physical, urinalysis, hematology, chemistries, serologies for coinfections, and patient education about HIV infection. An HIV resistance test is recommended upon initiation of care. After therapy is initiated, patients are generally monitored at 3-month intervals until HIV-RNA reaches undetectable levels. An assessment at 2 to 8 weeks is warranted to document early response. Monitoring may be increased to every 6 months in stabilized patients.

The two main indications for a change in therapy are significant toxicity and treatment failure. Should a single agent be responsible for an intolerable side effect that agent often can be singly changed out of the regimen. For example, the patient who experiences intolerable CNS disturbances during initiation of efavirenz can switch to a boosted PI or InSTI without changing the dual NRTI backbone. Maintaining virologic suppression is an important goal for switching therapy due to adverse events. Caution must be exercised when drugs in the regimen have overlapping toxicities, which makes changing a single agent problematic. Serious and life-threatening toxicities warrant cessation of the whole regimen before deciding upon a subsequent therapy.

As a general guide, the inability to achieve and maintain less than 200 copies/mL (200×10^3/L) of HIV-RNA represents treatment failure and should prompt consideration for changing therapy. This includes the inability to achieve less than 200 copies/mL (200×10^3/L) by 24 weeks of therapy initiation (repeat testing is suggested to confirm), or, after HIV-RNA suppression, repeated detection of greater than 200 copies/mL (200×10^3/L) of HIV-RNA.

Therapeutic Failure

⑨ The most important measure of therapeutic failure is suboptimal suppression of viral replication. Many reasons may underlie suboptimal suppression of viral replication such as pre-ART disease factors (eg, high viral load or pre-existing drug resistance), nonadherence to medication, development of new drug resistance, intolerance to one or more medications, adverse drug-drug or drug-food interactions, or pharmacokinetic-pharmacodynamic variability.[38] In cases of suboptimal suppression of viral replication, these potential causes should be investigated and addressed, if possible. As a general rule, drug resistance develops for regimens that do not maximally suppress HIV replication. Drug resistance testing is recommended while the patient is undergoing the failing regimen or within 4 weeks after stopping the regimen as long as the HIV-RNA count is greater than 500 copies/mL (500×10^3/L), which is the threshold for most resistance assays (~500-1,000 copies/mL [$\sim 500 \times 10^3$–1.0×10^6/L]). Virus may revert to wild type if more than 4 to 6 weeks has elapsed between regimen discontinuation and the resistance test. Most clinicians use the genotype assay because it is less expensive and results typically are available sooner compared with the phenotype assay. Resistance results usually require expert interpretation.

Treating patients who have drug-resistant HIV utilizes the same general treatment approaches described for initial therapy above. Several antiretroviral drugs are well-suited for drug-resistant HIV. The drugs in the newer classes (ie, InSTIs, entry inhibitors) are also active against NRTI-, NNRTI-, and PI-resistant viruses in highly treatment-experienced patients in controlled trials.[38] Patients should be treated with at least two (preferably three) fully active antiretroviral drugs from different mechanistic classes based on medication history and resistance tests. The goal of therapy is to suppress HIV-RNA to undetectable levels. In cases when undetectable HIV-RNA cannot be attained, maintenance on the regimen is preferred over drug discontinuation so as to prevent rapid immunological and clinical decline.

Prior to the availability of new drugs and drug classes, other strategies were studied to help manage therapeutic failure including drug holidays, structured or strategic treatment interruptions, and structured intermittent therapy. The overall premise of these strategies was similar: stop all antiretrovirals to spare the patient from drug toxicities and to allow the virus to revert to wild type. Reinitiation of therapy was intended to reestablish control of viral replication, as wild-type virus would be expected to predominate, although it was known that resistant virus was archived in long-lived cells, so viral suppression was short lived. Patients randomized to episodic therapy (drug-sparing) guided by the CD4 experienced significantly increased risk of opportunistic disease or death from any cause, including non-AIDS causes.[85,86] Viral replication is damaging to the immune system and end organs and drug-sparing approaches are not advocated.

HIV CURE RESEARCH

In 2007, the “Berlin patient,” a person with HIV and new-onset acute myeloid leukemia, underwent an allogeneic bone marrow transplant with homozygous CCR5delta32 stem cells.[87] Following a complicated clinical course, including graft versus host disease and second transplant, he was found to be free of HIV infection, as no virus could be detected in any sample tested in 2009. This was deemed a sterilizing cure and his case gave hope to researchers and patients alike for curing HIV infection. In 2019, a second person, the “London Patient”, has been reported as cured of HIV infection. Replicating these individuals treatment and clinical course, however, is not a practical or safe strategy for most persons living with HIV infection. Developing a cure will be particularly challenging because HIV integrates its genome into host cells, creating a latent reservoir. Thus, researchers have begun focusing on creating “functional cures,” where new treatments might allow patients to stop ART without disease progression. Ongoing clinical trials are evaluating such approaches.

COMPLICATIONS OF HIV INFECTION AND AIDS

③ In the pre-ART era, the major therapeutic focus was prevention and treatment of OIs associated with uncontrolled HIV replication and the steady decline in CD4 cells. Uncontrolled HIV is an insidious disease; persons often present with OIs, a consequence of the weakened immune system rather than HIV per se. Most OIs are caused by organisms that are common in the environment and often represent the reactivation of quiescent, hidden infections common in the population. The probability of developing specific OIs is closely related to CD4 count thresholds (Fig. 148-2). These CD4 thresholds serve as a basis for initiating primary OI chemoprevention.

FIGURE 148-2

Natural history of opportunistic infections associated with human immunodeficiency virus infection. CD4 counts expressed as cells/μL can be converted into SI units by multiplying by 10^6/L.

⑤ In the ART era, the main principle in the management of OIs is treating HIV infection to enable CD4 cell recovery and maintenance above protective levels.[65] Additional important principles regarding management of OIs are as follows:

1. Prevent exposure to opportunistic pathogens
2. Vaccinate to prevent first-episode disease (consult HIV-specific guidelines)
3. Use primary chemoprophylaxis at certain CD4 thresholds to prevent first-episode disease
4. Treat emergent OI
5. Use secondary chemoprophylaxis to prevent disease recurrence
6. Discontinue prophylaxes with sustained ART-associated immune recovery

Several considerations are required for the patient who presents with an OI and is simultaneously diagnosed with HIV and who thus needs both OI and ART treatment. Immediate initiation of ART is indicated for OIs that respond to CD4 recovery, such as cryptosporidiosis, progressive multifocal leukoencephalopathy (JC virus), and mild-to-moderate Kaposi's sarcoma (HHV8 virus). Rapid initiation of ART (within days to weeks) is also indicated in the setting of other OIs such as tuberculosis, *Mycobacterium avium* complex (MAC), and PCP, but several potential issues need consideration. First, drug-drug interactions and the complexity of adhering to concomitant ART and OI regimens can be daunting. Careful review of potential interactions and adherence support should be provided. Second, clinicians must be cognizant of potentially overlapping drug toxicities (eg, rash) that create problems when attempting to stop the perceived culprit drug. Third, an immune reconstitution inflammatory syndrome (IRIS) has been associated with initiation of ART in the presence of underlying OIs. IRIS is generally characterized by fever and worsening of OI manifestations in the first few weeks to months after initiating ART despite evidence of treatment efficacy. Risk factors for IRIS are a low CD4 count (eg, less than 50 cells/μL [0.050×10^9/L]) and a high antigenic burden. An ART-associated rapid-onset immune reconstitution against the smoldering OI infection, and resulting proinflammatory cytokine cascade, is the mechanism of IRIS. The most serious IRIS reactions involve neurological OIs such as cryptococcal meningitis, where IRIS can lead to increased morbidity and mortality. For cryptococcal meningitis, it may be prudent to delay ART until completion of the induction or induction/consolidation phase of antifungal therapy (up to 10 weeks). Generally, treatment of IRIS is supportive and may include corticosteroids and/or NSAIDs, depending on the OI. Expert consultation should be used in the management of ART initiation in patients with advanced HIV infection and OIs, and the most up-to-date guidelines should be consulted.

The epidemiology of specific OIs can depend upon geographical region.[49,65] For instance, TB is particularly endemic on the African continent and is considered a major OI in that region, but the incidence of TB is relatively uncommon in the United States. Major OIs in the United States include PCP, toxoplasmosis, MAC, cytomegalovirus retinitis, and cryptococcal meningitis. All have decreased substantially in incidence with the advent of ART.

Furthermore, primary and secondary chemoprophylaxis for specific OIs have contributed to the same decreases. Nevertheless, opportunistic diseases continue to be complications of HIV disease and occur at low CD4 lymphocyte counts in patients who are unaware of their HIV infection, or who have not responded to ART therapy or OI prophylaxis because of adherence issues or inadequate engagement with the healthcare system.

Selected OIs and recommended first-line regimens for OI treatment are given in Table 148-6. Recommended therapies for primary OI prophylaxis are given in Table 148-7.[65] These recommendations are representative and not as extensive as in the published guidelines, which include multiple additional treatment considerations and alternatives, as well as coverage of less common OIs. The following brief discussion of PCP provides a more in-depth overview of the epidemiology, diagnosis, clinical manifestations, and results of treatment and serves as an illustration for the principles discussed above.

TABLE 148-6

Selected Therapies for Common Opportunistic Pathogens in HIV-Infected Individuals

Clinical Disease	Preferred Initial Therapies for Acute Infection in Adults (Strength of Recommendation in Parentheses)	Common Drug- or Dose-Limiting Adverse Reactions
Fungi		
Candidiasis, oral	Fluconazole 100 mg orally for 7-14 days (AI) *Or* Nystatin 500,000 units oral swish (~5 mL) four times daily for 7-14 days (BII)	Elevated liver function tests, hepatotoxicity, nausea, and vomiting Taste, patient acceptance
Candidiasis, esophageal	Fluconazole 100-400 mg orally or IV daily for 14-21 days (AI) *Or* Itraconazole 200 mg/day orally for 14-21 days (AI)	Same as above Elevated liver function tests, hepatotoxicity, nausea, and vomiting
Pneumocystis jirovecii pneumonia	*Moderate to severe episodes* Trimethoprim–sulfamethoxazole IV or orally 15-20 mg/kg/day as trimethoprim component in three to four divided doses for 21 days[a] (AI) moderate or severe therapy should be started IV *Mild-to-moderate episodes* Trimethoprim–sulfamethoxazole 15-20 mg/kg/day as trimethoprim component orally in three divided doses or trimethoprim–sulfamethoxazole double strength tablets, two tablets three times daily	Skin rash, fever, leucopenia Thrombocytopenia
Cryptococcal meningitis	Liposomal amphotericin B 3-4 mg/kg/day IV with flucytosine 100 mg/kg/day orally in four divided doses for a minimum of 2 weeks (AI) *followed by*	Nephrotoxicity, hypokalemia, anemia, fever, chills Bone marrow suppression
	Fluconazole 800 mg/day, orally for 8 weeks. (AI)[a] Doses can be reduced to 400 mg po daily in clinically stable patients with negative CSF cultures. (AIII)[a]	Same as above
Histoplasmosis	Liposomal amphotericin B 3 mg/kg/day IV for 2 weeks (AI) *followed by*	Same as above
	Itraconazole 200 mg orally thrice daily for 3 days then twice daily, for 12 months (AII)[a]	

Coccidioidomycosis	Amphotericin B deoxycholate 0.7-1.0 mg/kg IV daily (AII) or lipid formulation amphotericin B 4-6 mg/kg IV daily (AIII) until clinical improvement, then switch to an azole (BIII) *Or* Fluconazole 400-800 mg IV or PO once daily (meningeal disease) (AII)[a]	Same as above Same as above
Protozoa		
Toxoplasmic encephalitis	Pyrimethamine 200 mg orally once, followed by weight-based therapy: ● If <60 kg, pyrimethamine 50 mg orally once daily ● If >60 kg, pyrimethamine 75 mg orally once daily Plus ● If <60 kg, sulfadiazine 1 g orally four times daily ● If >60 kg, sulfadiazine 1.5 g orally four times daily And Leucovorin 10-25 mg orally daily for 6 weeks (AI)[a]	Bone marrow suppression Rash, drug fever
Isosporiasis	Trimethoprim and sulfamethoxazole: 160 mg trimethoprim and 800 mg sulfamethoxazole orally or IV four times daily for 10 days (AII)[a]	Same as above
Bacteria		
Mycobacterium avium complex	Clarithromycin 500 mg orally twice daily, *plus* ethambutol 15 mg/kg/day orally (AI) for at least 12 months	GI intolerance, optic neuritis, peripheral neuritis, elevated liver tests
Salmonella enterocolitis or bacteremia	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 14 days (longer duration for bacteremia or advanced HIV) (AIII)	GI intolerance, headache, dizziness
Campylobacter enterocolitis (mild to moderate)	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 7-10 days (or longer with bacteremia) (BIII)	Same as above
Shigella enterocolitis	Ciprofloxacin 500-750 mg orally (or 400 mg IV) twice daily for 7-10 days (or >14 days for bacteremia) (AIII)	Same as above
Viruses		
Mucocutaneous herpes simplex	Acyclovir 5 mg/kg IV every 8 hr until lesions regress, then acyclovir 400 mg orally three times daily until complete healing (famciclovir or valacyclovir is alternative) (AIII)	GI intolerance, crystalluria
Primary varicella-zoster	Acyclovir 10-15 mg/kg every 8 hr IV for 7-10 days (severe cases), then switch to oral valacyclovir 1 g three times daily after defervescence if no evidence of visceral involvement (famciclovir or acyclovir is alternative) (AIII)	Obstructive nephropathy, CNS symptoms
Cytomegalovirus (retinitis)	Ganciclovir 5 mg/kg Q12H IV or valganciclovir 900 mg orally twice daily for 14-21 days (AI) with or without: Intravitreal ganciclovir (2 mg) or foscarnet (2.4 mg) for 1-4 doses over 7-10 days (for sight	Neutropenia, thrombocytopenia

	threatening lesions) *plus* valganciclovir 900 mg twice daily for 14-21 days then once daily until immune recovery from ART (AIII)[a]	
Cytomegalovirus esophagitis or colitis	Ganciclovir 5 mg/kg IV every 12 hr for 21-42 days; may switch to valganciclovir 900 mg orally every 12 hr when oral therapy can be tolerated (BI)	Same as above

[a]Maintenance therapy is recommended.

ART, antiretroviral therapy; CSF, cerebrospinal fluid; HIV, human immunodeficiency virus.

See Table 126-3 for levels of evidence-based recommendations.

TABLE 148-7

Therapies for Prophylaxis of Select First-Episode Opportunistic Diseases in Adults and Adolescents

Pathogen	Indication	First Choice (Strength of Recommendation in Parentheses)
Standard of care		
Pneumocystis jirovecii	CD4$^+$ count <200/mm^3 (<0.2 × 10^9/L) *or* oropharyngeal candidiasis	Trimethoprim–sulfamethoxazole, one double-strength tablet orally once daily (AI) or one single-strength tablet orally once daily (AI)
Histoplasma capsulatum	CD4$^+$ count <150/mm^3, (<0.15 × 10^9/L) endemic geographic area and high risk for exposures	Intraconazole 200 mg orally once daily (BI)
Mycobacterium tuberculosis		
Isoniazid-sensitive	(Active TB should be ruled out): positive test for latent TB infection with no prior TB treatment history (AI) *or* negative test for latent TB infection, but close contact with case of active tuberculosis (AII)	Isoniazid 300 mg orally plus pyridoxine, 25 mg orally once daily for 9 months (AII) *Or* Rifapentine (weight-based) oral plus INH 900 mg oral plus pyridoxine 50 mg oral once weekly for 12 weeks (AII) Rifapentine Weekly Dose: ○ 32.1-49.9 kg: 750 mg ○ >50 kg: 900 mg Or 600 mg oral daily for 4 months Rifapentine only recommended for persons receiving RAL or EFV-based ART regimen
For exposure to drug-resistant	Consult public health authorities	

TB		
Toxoplasma gondii	Immunoglobulin G antibody to *Toxoplasma* and CD4$^+$ count <100/mm^3 (<0.1 × 10^9/L)	Trimethoprim–sulfamethoxazole one double-strength tablet orally once daily (AII)
Mycobacterium avium complex	CD4$^+$ count <50/mm^3 (<0.05 × 10^9/L)	Azithromycin 1,200 mg orally once weekly (AI) or 600 mg orally twice weekly (BIII) or clarithromycin 500 mg orally twice daily (AI)
Varicella zoster virus (VZV)	Preexposure: CD4 ≥200/mm^3 (≥0.2 × 10^9/L), no history of varicella vaccination or infection, or, if available, negative antibody to VZV Postexposure: Significant exposure to chicken pox or shingles for patients who have no history of vaccination or either condition or, if available, negative antibody to VZV	Varicella vaccination; two doses, 3 months apart (BIII) Varicella-zoster immune globulin, 125 IU per 10 kg (maximum of 625 IU) IM, as soon as possible and within 10 days after exposure (AIII)
Streptococcus pneumoniae	Any individual regardless of CD4 count	13-valent polysaccharide vaccine, 0.5 mL intramuscularly once (AI) followed by 23-valent polysaccharide vaccine 0.5 mL 8 weeks later (CIII) Re-vaccinate with PPV23 0.5 mL IM one time (BII) if the following: ○ Aged 19-64 years and >5 years since first PPV23 dose ○ Final dose to be given at >65 years, and if >5 years since the previous PPV23 dose ○ Typically, no more than 3 doses of PPV23 in a lifetime
Hepatitis B virus	All susceptible patients	HBV vaccine IM (Engerix-B 20 μg/mL or Recombivax HB 10 μg/mL), 0, 1, and 6 months (AII) Anti-HBs should be obtained 1 month after the vaccine series completion (BIII)
Influenza virus	All patients (annually, before influenza season)	Inactivated trivalent influenza virus vaccine (annual): 0.5 mL intramuscularly (AIII) (live-attenuated vaccine is contraindicated in all persons with HIV)
Hepatitis A virus	All susceptible (anti-hepatitis A virus–negative) patients at increased risk for hepatitis A infection (eg, chronic liver disease, injection drug users, men who have sex with men)	Hepatitis A vaccine: two doses at 0 and 6-12 months (AII) antibody response should be assessed 1 month after vaccination; with revaccination as needed when CD4 >200 cells/μL (>0.2 × 10^9/L)(BIII)
Human papillomavirus (HPV) infection	Target age for vaccination: 11-12 years (AIII) Vaccination through age 26 is recommended but vaccine effectiveness is lower if vaccination occurs after onset of sexual activity (BII)	HPV recombinantvaccine 9 valent intramuscularly at months 0, 1-2, and 6 (BIII)

See Table 126-3 for levels of evidence-based recommendations.

Data from Reference [66].

Pneumocystis jirovecii Pneumonia

5 *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP) is the most common life- threatening OI in patients with AIDS.[88] *P. jirovecii* was formerly named *P. carinii*; the name change was made to distinguish the organism that infects humans (*P. jirovecii*) from the strain that infects rodents (*P. carinii*). Nevertheless, the acronym PCP is still used today. PCP was common early in the AIDS epidemic, but the incidence of PCP has fallen markedly since the advent of ART and effective prophylaxis for PCP. It still occurs in persons unaware of their HIV infection, and breakthrough PCP can occur in those with variable adherence to ART and/or prophylaxis.

P. jirovecii is a fungus that has protozoan characteristics as well.[88] Exposure to *P. jirovecii* is widespread; two-thirds of the population have developed serum antibodies by age 2 to 4 years. The organism resides without consequence in humans unless the host becomes immunologically impaired.[88] Disease associated with immunosuppression probably occurs from both new acquisition and reactivation. Ninety percent of PCP cases in AIDS patients occurred in those with CD4 counts less than 200 cells/mm^3 (0.2×10^9/L).[65] Other risk factors include oral thrush, recurrent bacterial pneumonia, unintentional weight loss, and high-plasma HIV-RNA. Past episodes of PCP increase risk for future episodes, which provides the basis for secondary chemoprophylaxis, as described below.

The presentation of PCP in AIDS often is insidious.[88] Characteristic symptoms include fever and dyspnea. Clinical signs are tachypnea with or without rales or rhonchi and a nonproductive or mildly productive cough occurring over a period of weeks, although more fulminant presentations can occur. Chest radiographs may show florid or subtle interstitial and bilateral infiltrates but occasionally are normal. Arterial blood gases may show minimal hypoxia (PaO_2, 80-95 mm Hg [10.6-12.6 kPa]) but in more advanced disease may be markedly abnormal. The diagnosis of PCP usually is made by identification of the organism in induced sputum or in specimens obtained from bronchoalveolar lavage. Less commonly, transbronchial or open lung biopsy is used to locate the organism. The stain used for organism identification affects the sensitivity and specificity of the respiratory samples. Many laboratories prefer direct immunofluorescent staining using monoclonal antibodies. PCR is an alternative diagnostic method that is highly sensitive and specific for detecting *Pneumocystis.* Unfortunately, PCR does not distinguish whether the presence of the organism is due to colonization or disease. 1,3-β-D-glucan is a component of *Pneumocystis* cell walls that is elevated in patients with PCP. The assay for 1,3-β-D-glucan has a high sensitivity for those with PCP and can therefore be used to rule out PCP, but it is nonspecific because elevation may also be due to various causes, including other fungal infections.[65]

Untreated PCP has a mortality rate of nearly 100%. Several potential treatments are available for PCP, but the treatment of choice is trimethoprim–sulfamethoxazole (also called cotrimoxazole), which is associated with a response rate of 60% to 100%.[65] Parenteral pentamidine is equally efficacious but significantly more toxic. Trimethoprim–sulfamethoxazole is also the regimen of choice for primary and secondary prophylaxis of PCP in patients with and without HIV.[65] Additional drugs, such as echinocandins, and vaccines are in development for PCP.[89]

When used for treatment of PCP, the dose of trimethoprim–sulfamethoxazole is 15 to 20 mg/kg/day (based on the trimethoprim component) as three to four divided doses. Treatment duration typically is 21 days but also must be based on clinical response. Trimethoprim–sulfamethoxazole is usually initiated by the IV route, although oral therapy may suffice in mildly ill and reliable outpatients or for completion of a course of therapy after a response has been achieved with IV administration.[65,89] Patients with moderate-to-severe PCP (eg, PaO_2 more than 70 mm Hg [9.3 kPa]) should be treated with corticosteroids as soon as possible after starting PCP therapy and certainly within 72 hours, in order to blunt the deterioration seen just after initiation of PCP therapy. Alternative regimens include primaquine with clindamycin or IV pentamidine for moderate-to-severe disease, and dapsone with trimethoprim, primaquine with clindamycin, or atovaquone for mild-to-moderate PCP.[65] Early initiation of ART (within 2 weeks) is recommended, keeping in mind the potential issues described earlier.

Adverse reactions to trimethoprim–sulfamethoxazole and pentamidine are common, occurring in 20% to 85% of patients in this setting.[65] The more common adverse reactions seen with trimethoprim–sulfamethoxazole are rash (rarely including Stevens–Johnson syndrome), fever, leukopenia, elevated serum transaminase levels, and thrombocytopenia. The incidence of these adverse reactions is higher in persons with HIV than in those not infected with HIV. Mild rashes should be watched closely for progression to more severe reactions but are not an absolute contraindication to continuing therapy. This highlights the need for thoughtful consideration of ART components because of overlapping toxicities with some antiretrovirals such as NNRTIs, which are also associated with rash and hypersensitivity, including life-threatening cases. Alternative treatments can have their own side effect profiles to consider. Dosage modification or pharmacokinetic monitoring can reduce the toxicity of trimethoprim–sulfamethoxazole. Early addition of adjunctive corticosteroid therapy to anti-PCP regimens decreases the risk of respiratory failure and improves survival. The adverse effects associated with corticosteroid use for this scenario are minimal, primarily an increased incidence of herpetic lesions, although some concerns exist about the potential for reactivation of tuberculosis or cytomegalovirus and/or long-term effects on bones.

Prevention of PCP is clearly a preferable treatment strategy. Primary prophylaxis is recommended for any person with HIV who has a CD4 lymphocyte count less than 200 cells/mm^3 (0.2 × 10^9/L) (or CD4 percentage of total lymphocytes less than 14% [0.14]) or a history of oropharyngeal candidiasis.[65,88] Secondary PCP prophylaxis is recommended for all persons with HIV who have had a previous episode of PCP. Trimethoprim–sulfamethoxazole is the most effective and least expensive agent and is the preferred therapy for both primary and secondary prophylaxis of PCP in adults and adolescents.[65,88] It also confers cross-protection against toxoplasmosis and many bacterial infections. The recommended dose in adults and adolescents is one double-strength tablet daily, although other regimens, such as one double-strength tablet thrice weekly or one single-strength tablet daily and gradual dose escalation using liquid trimethoprim–sulfamethoxazole, have been used to reduce the incidence of adverse reactions and improve adherence. Alternative prophylactic regimens are available if trimethoprim–sulfamethoxazole cannot be tolerated.

In the ART era, the profound reduction in HIV replication and restoration in CD4 cell count to levels rarely associated with the development of OIs provides a basis for the discontinuation of primary and secondary prophylaxis.[65] For PCP, primary prophylaxis should be discontinued in patients receiving and responding to ART who have a CD4 cell count greater than 200 cells/mm^3 (0.2 × 10^9/L) sustained for at least 3 months, but should be reinstated if the CD4 count drops to less than 200 cells/mm^3 (0.2 × 10^9/L). The same criteria apply for both discontinuation and reinitiation of secondary prophylaxis of PCP. However, continued secondary prophylaxis should be considered when the original PCP episode occurred at a CD4 count greater than 200 cells/mm^3 (0.2 × 10^9/L).

Comprehensive recommendations are available for management of PCP and other OIs in the context of HIV infection, including prophylaxis, treatment, and removal of prophylaxis with the control of HIV infection.[65] Readers are advised that data continue to emerge on new OI therapies, the safety of stopping primary and secondary prophylaxis, as well as criteria for when to restart secondary prophylaxis. The most current guidelines should always be consulted. Similar OI guidelines specific to children have been developed and are updated regularly.[43]

The Aging HIV Population

9 Given the life-prolonging effects of ART, approximately half of persons with HIV are over 50 years of age in resource-rich countries.[90] Along with older age come higher rates of well-known chronic and acute illnesses such as osteoporosis and osteopenia, renal and hepatic insufficiency, metabolic syndrome, neurocognitive decline, atherosclerotic disease, frailty, and non-AIDS malignancies. Many of these illnesses occur at higher than expected rates in older persons with HIV in the ART era.[91,92] The cause(s) of these higher rates is the focus of intense study. Initially, adverse events from antiretroviral medications such as hyperlipidemia were thought to contribute significantly to these conditions but ongoing inflammation and viral persistence play a critical role. Therefore, ART generally protects against non-AIDS events and it is universally recommended to manage these emerging complications. Additionally, persons with HIV should adopt healthy habits to slow the aging process including healthy diets, regular exercise, and adequate sleep.

One-third of deaths in people living with HIV are attributed to cancer.[93] While contemporary ART has reduced the incidence of HIV-related cancers such as Kaposi’s sarcoma and non-Hodgkin’s lymphoma, other non-AIDS-related malignancies impact persons with HIV at significantly elevated rates such as Hodgkin’s lymphoma and anal, lung, skin, and hepato-carcinoma. Part of this risk may be attributed to elevated exposures or susceptibilities to human papillomavirus (oral and anal cancer), smoking (lung carcinoma), and chronic hepatitis B and/or C coinfection (liver cancer), which are modifiable risk factors. For example, guidelines advocate HPV vaccination for younger persons with HIV, as well as increased screening for anal cancer in those with existing genital or anal warts.[65] Antiretroviral drugs may contribute directly to these increased cancer rates, as some agents have been associated with cancers in observational studies.[94] However, persisting immunosuppression may be an underlying cause of higher cancer rates in persons with HIV.[91] While the approach to treatment of non-AIDS-related malignancies in persons with HIV is similar to that in persons without HIV, treatment is complicated by drug-drug interactions or additive toxicities that may exist between the antiretrovirals and the oncolytics.[95]

Cardiovascular disease has also emerged as a major concern for persons with HIV. Persons with HIV are at higher risk of cardiovascular disease compared with persons without HIV, including persons with viral suppression.[91] This increased risk is similar in magnitude to other well-established risk factors such as hypertension and hyperlipidemia. Elevated systemic inflammation and its impact on endothelial structure and function and the clotting cascade is thought to underlie much of this risk, as elevations in circulating C-reactive protein and IL-6 correlate with clinical outcomes. Statins are beneficial in persons with HIV and dyslipidemia, in part because of their anti-inflammatory effects. In this population, pitavastatin reduced markers of arterial inflammation and immune system activation.[96] Antiretroviral drugs themselves may also contribute to cardiovascular risk, given the well-known relationships between PIs, efavirenz, and certain NRTIs with dyslipidemia (increased triglycerides and low-density lipoproteins [LDL] and decreased high-density lipoproteins [HDL]) and abnormal glucose homeostasis (insulin resistance and impaired glucose tolerance).[91] Retrospective studies have found an association between myocardial infarction and abacavir use, but other studies have not, so this association is controversial and highlights the difficulty in using observational and retrospective data to attribute risk to these emerging medical conditions. Tenofovir alafenamide has been associated with lipid increases in comparison to tenofovir disoproxil,[56] though it is unclear whether tenofovir disoproxil has lipid-lowering properties or if tenofovir alafenamide is involved in mechanistically causing these increases.[91] Metabolic abnormalities in persons with HIV on ART, such as hyperlipidemia and hyperglycemia, should be reviewed with consideration given towards optimizing ART where possible to minimize side effects and avoid drug-drug interactions.

Another relevant problem for persons with HIV is body fat abnormalities. Older ART was associated with changes in body fat distribution[97] and newer ART options, such as InSTIs and tenofovir alafenamide, have been associated with weight gain. The thymidine analogs, particularly stavudine, were associated with lipoatrophy of the subcutaneous fat in the extremities and face, and these agents and older PIs were associated with hypertrophy of the deep abdominal fat depot. Collectively these fat abnormalities were termed HIV lipodystrophy. Newer agents areless associated with lipodystrophy compared with older agents, which provides a basis for switching therapy to newer regimens or initiating therapy with preferred regimens. The best management of body fat changes is prevention through initiation of preferred regimens less likely to cause such changes (see current recommendations for initial therapy, Table 148-2).[65] The weight gain with InSTIs and tenofovir alafenamide is a separate issue from lipodystrophy seen with older ARV medications. The greatest weight gain was with InSTIs (dolutegravir ~ bictegravir > raltegravir > elvitegravir), followed by PIs, and then NNRTIs.[62,63] Tenofovir alafenamide has also been associated with greater weight gain than tenofovir disoproxil fumarate,[56] and this effect is more pronounced when combined with dolutegravir. A clear underlying mechanism has not been established, and some studies have also failed to identify associations.

Functional declines of end organs such as kidney, liver, skeletal muscle (frailty), and brain (cognition) are other important considerations for older persons with HIV. These declines are expected with aging but are related with HIV itself.[91] However, certain drugs may also exacerbate these issues. The NNRTI efavirenz, for instance, is commonly associated with central nervous system perturbations including somnolence, attention deficits, and psychiatric issues. These effects exacerbate neurocognitive impairment, although this is controversial and difficult to disentangle from the effects of HIV. Similarly, integrase inhibitors have been associated with neuropsychiatric side effects, such as insomnia, worsening depression, and increased suicidality, particularly among those with pre-existing psychiatric conditions. These effects have primarily been analyzed with dolutegravir, with risk factors including preexisting conditions, age over 60 years, female sex, and the concomitant use of abacavir.[98] The most important defense against HIV-associated neurocognitive decline is durable suppression of viral replication.[99]

HIV also causes a nephropathy (termed HIV-associated nephropathy, or HIVAN), most commonly a glomerulopathy that can lead to end-stage renal disease in the absence of ART.[100] The incidence of this condition has declined by approximately 60% in the ART era, demonstrating that ART is the most important intervention against HIVAN. Black people are more likely to experience HIVAN compared with White people. Some antiretroviral drugs impact renal health and these may exacerbate the effects of HIV. For example, atazanavir and lopinavir may crystallize in urine leading to obstruction, whereas tenofovir may injure the proximal tubule leading to Fanconi syndrome in rare cases.[101] The newer tenofovir alafenamide pro-drug is less likely to cause proximal tubulopathy because plasma concentrations of tenofovir are lower compared with tenofovir disoproxil.[74] Renal function should be monitored routinely in all persons with HIV, including consideration for more frequent monitoring for patients receiving the drugs mentioned above.[38]

Persons with HIV experience coinfection with hepatitis B (HBV) and hepatitis C virus (HCV) relatively commonly, and this can drive declines in hepatic function in this population.[65] For example, up to 30% of persons with HIV in the United States have HIV-HCV (~300,000 individuals) including as many as 90% of persons who use injection drugs and 90% of persons with hemophilia. HIV worsens the prognosis of HCV by reducing the chance of HCV clearance and accelerating HCV progression. With chronic HCV infection, progression to fibrosis, cirrhosis, and liver failure is several-fold faster in HIV-

HCV patients versus HCV-monoinfected patients. ART reduces progression to hepatic decompensation and, among HIV-HCV coinfected population on ART, progression is faster in those who do not fully suppress HIV replication. For these reasons, ART is recommended for HIV-HCV coinfected persons and HCV therapy should be offered according to HCV guidelines.[102] The most important consideration for co-treatment is potential drug-drug interactions between ART and HCV therapies. Again, the most recent information should be consulted in reviewing potential interactions.[38,102]

The same general principles extend to HIV-HBV coinfected patients, who comprise approximately 10% of the HIV population.[65] However, two unique considerations are relevant for HIV-HBV coinfection. First, the ART regimen should include tenofovir (in the form of tenofovir disoproxil or alafenamide) plus either lamivudine or emtricitabine, given the HBV activity of these agents. Second, hepatic flares and decompensation has been reported when tenofovir-based therapy was interrupted or discontinued. If discontinuation is necessary, close monitoring of hepatic function is indicated.

Despite these issues in the contemporary ART era, the pharmacotherapy of HIV infection has steadily improved over the past 30 years, such that HIV is now a chronic but manageable condition. Whether the patient will ultimately mount a durable response to ART depends upon adherence, convenience/tolerability, and pharmacologic effectiveness. As discussed throughout this chapter, a large number of considerations go into choosing the optimal ART for a given patient. These factors include pre-ART disease characteristics (eg, resistance testing, viral load, and CD4 count), ART characteristics (eg, coformulations, food requirements, drug–drug interactions), comorbid conditions (eg, pre-existing renal dysfunction), potential for pregnancy, HLA-B*5701 and/or tropism testing (if abacavir or maraviroc are being considered), and co infections (eg, TB infection). The clinician's knowledge and application of HIV pathophysiology and pharmacologic principles of ART will ultimately guide therapeutic success.

ACKNOWLEDGMENTS

The authors wish to thank Drs. Thomas Kakuda and Jenna Yager for their invaluable contributions and efforts on previous editions of this chapter and Cecilia Nguyen for help with the OI tables. This work was supported by Grants R01 AI122298, UM1 AI06701, R01 HD085887, and R01 AI124965 from the National Institute of Allergy and Infectious Disease.

ABBREVIATIONS

AIDS	acquired immunodeficiency syndrome
ART	antiretroviral therapy
CCR5	chemokine (C–C motif) receptor 5
CD	cluster of differentiation
CDC	Centers for Disease Control and Prevention
CXCR4	chemokine (C–X–C motif) receptor 4
CYP	cytochrome P450
DHHS	Department of Health and Human Services
ELISA	enzyme-linked immunosorbent assay
FDA	Food and Drug Administration
gp	glycoprotein
HCV	hepatitis C virus

HDL	high-density lipoprotein
HIV	human immunodeficiency virus
HIVAN	HIV-associated nephropathy
HLA	human leukocyte antigen
IC_{50}	concentration of antiretroviral agent necessary to inhibit 50% of viral replication
Ig	immunoglobulin
InSTI	integrase strand transfer inhibitor
IRIS	immune reconstitution inflammatory syndrome
LDL	low-density lipoprotein
LTR	long-terminal repeat
MAC	*Mycobacterium avium* complex
MSM	men who have sex with men
NNRTI	nonnucleoside reverse transcriptase inhibitor
NRTI	nucleoside/nucleotide reverse transcriptase inhibitor
OI	opportunistic infection
PCP	*Pneumocystis jirovecii* (*carinii*) pneumonia
PCR	polymerase chain reaction
PI	protease inhibitor
PEP	postexposure prophylaxis
PrEP	preexposure prophylaxis
RT-PCR	reverse-transcription polymerase chain reaction
SIV	simian immunodeficiency virus
TB	tuberculosis
TAF	tenofovir alafenamide
TDF	tenofovir disoproxil fumarate
WHO	World Health Organization

SELF-ASSESSMENT QUESTIONS

1. Which of the following statements regarding the management of *Pneumocystis jirovecii* pneumonia is true?
    - A. Untreated PCP has a mortality rate of approximately 20%.
    - B. Sulfamethoxazole–trimethoprim is dosed based on the sulfamethoxazole component.
    - C. Primary prophylaxis is recommended for patients with fewer than 100 CD4 cells/μL (0.1×10^9/L).
    - D. Moderate-to-severe disease should be treated with adjunctive corticosteroids.
2. Which of the following regarding the molecular characteristics of HIV is false?
    - A. HIV is a single-stranded RNA virus.
    - B. HIV-2 is the predominant type found in the United States.
    - C. There are multiple clades (subtypes) that further distinguish the HIV viruses.
    - D. HIV is believed to have originated from a cross-species transmission of a simian immunodeficiency virus from primates to humans.
3. Which of the following are AIDS-defining illnesses? (Select all that apply)
    - A. Esophageal candidiasis
    - B. *Mycobacterium tuberculosis*
    - C. Rhinovirus
    - D. Syphilis
4. Which of the following is false regarding the integrase strand transfer inhibitors (InSTI)?
    - A. They are relatively well-tolerated compared with other antiretroviral drugs.
    - B. Dolutegravir has a higher genetic barrier to resistance compared with elvitegravir and raltegravir.
    - C. They are mainly excreted as unchanged drug in urine.
    - D. They are recommended as part of first-line ART regimens.
5. Which of the following is not an accurate characterization of the HIV epidemic?
    - A. HIV infections are most concentrated in sub-Saharan Africa.
    - B. The main risk factor for females is heterosexual intercourse.
    - C. The main risk factor for HIV worldwide is men who have sex with men.
    - D. Approximately 38 million humans have HIV infection worldwide.
6. Which one of the following statements regarding HIV drug resistance is false?
    - A. A phenotype assay measures the in vitro drug concentration needed for inhibition of the patient's viral isolate.
    - B. A genotype assay measures the genetic makeup of the patient's virus and reports the important mutations found

C. Nonnucleoside analog reverse transcriptase inhibitors are susceptible to a single genetic mutation in HIV that extends cross-resistance to the class (except etravirine or doravirine).

D. The protease inhibitors class is susceptible to a single genetic mutation in HIV that extends cross- resistance to the class (low genetic barrier).

7. Which of the following statements regarding the transmission of HIV is false?

A. Receptive sexual intercourse carries higher risk for HIV acquisition compared with insertive intercourse.

B. Persons with HIV on ART with an undetectable HIV-RNA do not transmit HIV to others through sex (U=U).

C. Encouraging safer sex practices is a major component in preventing sexual transmission.

D. The presence of genital ulcers or sexually transmitted infections does not increase the risk for contracting HIV.

8. Which of the following is true regarding postexposure prophylaxis (PEP)?

A. PEP is available after both occupational and other non-occupational, high-risk HIV exposure.

B. PEP consists of two ART agents.

C. Two weeks of PEP therapy is advised following exposure.

D. PEP initiation should be delayed while waiting on the HIV status of the source.

9. Which is true regarding pre-exposure prophylaxis (PrEP)?

A. PrEP using 2:1:1 dosing should be recommended for all modes of HIV transmission.

B. PrEP consists of three drug regimens given for one month.

C. HIV acquisition during long-acting PrEP with cabotegravir may be associated with delayed seroconversion.

D. PrEP can be started while waiting for an HIV negative test.

10. Which of the following steps in the HIV life cycle establishes lifelong infection?

A. Adsorption and penetration

B. Reverse transcription

C. Viral maturation

D. Integration

11. Which of the following are true regarding the monitoring of therapeutic outcomes following ART initiation? (Select all that apply)

A. Plasma HIV-RNA and CD4 are the primary tests used to evaluate response.

B. If a single agent is responsible for toxicity, all agents in the regimen should be changed.

C. Treatment failure is generally defined as the inability to achieve and maintain virologic suppression.

D. Once a patient’s immune system has been restored (increased CD4 cell count), ART may be held until the CD4 count is less than 250 cells/μL (0.25×10^9/L) without any long-term risk to the patient.

12. Which of the following is the most important drug-drug interaction issue specific to cobicistat or ritonavir?

A. Concomitant acid suppression with proton pump inhibitors

B. Concomitant drugs that undergo extensive CYP3A4 metabolism

C. Concomitant drugs that undergo extensive renal clearance via filtration

D. Concomitant drugs that undergo extensive glucuronidation via UGT1A1

13. Which of the following is false regarding ART use during pregnancy and lactation?

A. The goal is to suppress HIV replication to undetectable levels.

B. Pregnancy can be associated with altered antiretroviral drug pharmacokinetics.

C. Prophylaxis for the infant may be warranted.

D. Breastfeeding is recommended in the United States.

14. Which of the following characteristics is best representative of the nucleoside analog reverse transcriptase (NRTI) inhibitor class?

A. Significant drug-drug interaction potential with cytochrome P450 (CYP450) substrates.

B. A single mutation in HIV reverse transcriptase gene causes cross-resistance to the whole class.

C. The drugs enter cells, become phosphorylated to the active triphosphate anabolite, and inhibit HIV reverse transcriptase.

D. Most are extensively metabolized by the liver.

15. Which of the following is/are false regarding chronic illnesses that have emerged in the ART-era? (Select all that apply)

A. HIV-related cancers have emerged as a leading cause of mortality and morbidity in the ART-era.

B. Patients with HIV infection are at a lower risk for cardiovascular disease compared to HIV-negative individuals.

C. As much as half of the HIV population is over 50 years old in resource-rich countries.

D. Hepatitis C coinfection is rare and should not be treated in patients taking ART.

SELF-ASSESSMENT QUESTION-ANSWERS

1. **D**. Adjunctive corticosteroids are recommended in moderate-to-severe disease. Untreated PCP has a mortality rate of nearly 100%, based on the trimethoprim component, and primary prophylaxis is indicated when the CD4 cell count is <200 cells/μL (0.2 x 10^9/L). See the “Pneumocystis jirovecii Pneumonia” section for additional information.

2. **B**. HIV-1 is the predominant type found in the United States. See the “Etiology” and “Detection of HIV and Surrogate Markers of Disease Progression” sections for more information.

3. **A, B**. Rhinovirus (C) causes the common cold and syphilis (D) is a sexually transmitted infection. Though both of these conditions can occur in persons with HIV, neither of these are AIDS-defining conditions. See Table 148-1 for a list of AIDS-defining conditions.

4. **C**. InSTIs are metabolized by CYP3A4 and/or UGT1A1. See the “Antiretroviral Agents” and “Drug Interactions” sections for more information.

5. **C**. Though MSM account for the majority of new HIV cases, this is subsequent to unprotected receptive anorectal intercourse. See the “Epidemiology”section for more information.

6. **D**. Protease inhibitors (notably atazanavir and darunavir) have higher genetic barriers to resistance and typically require multiple mutations to become ineffective. See the “Antiretroviral Agents” section for more information.

7. **D**. The presence of genital ulcers and other sexually transmitted diseases increases the risk of HIV transmission.

8. **A**. PEP consists of at least three antiretroviral medications, should be continued for 4 weeks, and should be initiated as soon as possible (within a maximum of 72 hours) after potential exposure. See the "Post-Exposure Prophylaxis" section for more information.

9. **C**. 2:1:1 Dosing is only recommended in MSM engaging in receptive anal sex. PrEP only consists of 1 to 2 antiretroviral drugs (either long-acting cabotegravir or emtricitabine/tenofovir in the form of either tenofovir alafenamide or tenofovir disoproxil fumarate), and should NOT be initiated until negative HIV infection is confirmed to prevent drug resistance mutations with subtherapeutic HIV therapy. See the "Pre-Exposure Prophylaxis" section for more information.

10. **D**. Integration refers to the insertion of reverse-transcribed, double-stranded HIV DNA by the HIV integrase enzyme into the host cell's genome. This is a key step in establishing lifelong HIV infection. See the "Pathogenesis" section for more information.

11. **A, C**. If a single agent is responsible for toxicity, then only the single agent needs to be changed, not the entire regimen. HIV requires lifelong therapy and should not be discontinued once the CD4 count increases – cessation of ART would result in viral load rebound and a CD4 count drop, placing the individual at risk of increased HIV-associated morbidity and mortality. See the "General Approach to Treatment" section for more information.

12. **B**. Cobicistat and ritonavir are potent inhibitors of CYP3A4, and thus cause several drug-drug interactions through this pathway. See the "Drug Interactions" section for more information.

13. **D**. Breastfeeding is not recommended in the United States due to concerns over the risk of HIV transmission and availability of formula. See the "Pregnancy" section for more information.

14. **C**. This class of drugs has a low potential to cause or be susceptible to drug-drug interactions, and generally multiple mutations are required to make the entire class ineffective. N(t)RTIs are primarily renally eliminated unchanged (except for abacavir), and thus are not metabolized by the liver. See the "Antiretroviral Agents" and "Drug Interactions" sections for more information.

15. **A, B, D**. Non-HIV related cancers are more commonly encountered, persons with HIV are at higher risk of cardiovascular disease, and hepatitis C is a commonly encountered coinfection in persons with HIV that should be treated. See the "The Aging HIV Population" section for more information.

Chapter 149: Cancer: The Disease and Treatment

Lisa M. Cordes; Sandra Cuellar

KEY CONCEPTS

KEY CONCEPTS

① Carcinogenesis is a multistep process that includes initiation, promotion, conversion, and progression.

② Cancer cells demonstrate unique traits that distinguish them from normal cells. Cancer cells can stimulate their own growth, resist inhibitory signals, avoid programmed cell death, grow new blood vessels (angiogenesis), invade local tissues, and spread to distant sites (ie, metastases).

③ Screening programs are designed to detect cancers in asymptomatic people who are at risk of a specific cancer.

④ Diagnosis and staging inform the treatment goals and help select the most appropriate anticancer therapy. The treatment goal may be cure, control, or palliation. The therapy may include a combination of surgery, radiation therapy, or systemic anticancer agents. Systemic anticancer agents include chemotherapy, targeted agents, and immunotherapy.

⑤ Chemotherapy inhibits cancer growth by killing rapidly proliferating cells. These agents can be categorized as either cell-cycle phase-specific, targeting one specific phase of the cell cycle, or cell-cycle phase-nonspecific, targeting all proliferating cells regardless of their place in the cell cycle. Cell-cycle phase-specific chemotherapy is generally administered more frequently or as a continuous infusion, and cell-cycle phase-nonspecific chemotherapy is usually administered less frequently.

⑥ Small-molecule targeted agents inhibit kinases or enzymes responsible for activating various proteins involved in intracellular signaling cascades. These agents treat cancer by correcting a dysregulated signaling pathway.

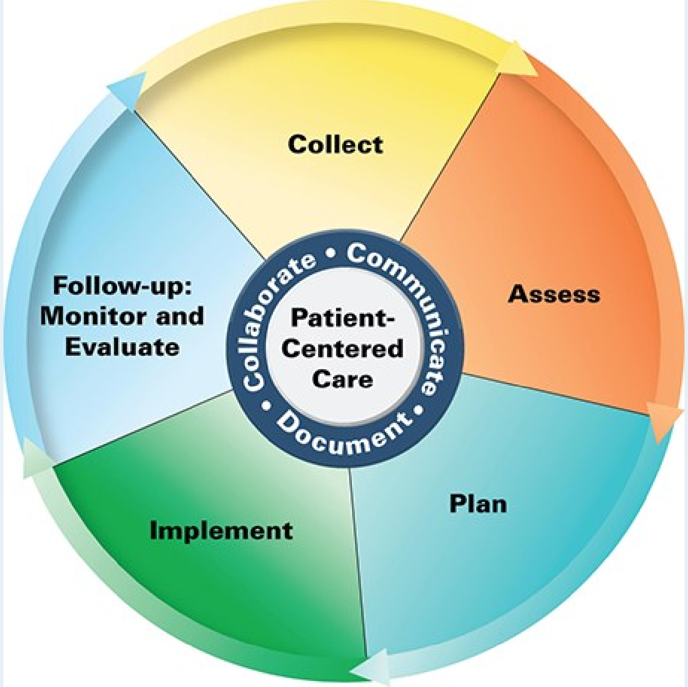
⑦ A monoclonal antibody (mAb) is a type of targeted therapy that recognizes an antigen preferentially expressed on cancer cells or immune cells or that targets growth factors responsible for cancer growth. These antibodies can also be used to deliver drugs, radioisotopes, or toxins to the antigen-expressing cells.

⑧ Immunotherapies are anticancer treatments that simulate or restore the immune system to recognize and eliminate cancer cells. Immune checkpoint inhibitors, cytokines, therapeutic vaccines, and chimeric antigen receptor (CAR) T-cell therapies are types of immunotherapies.

⑨ Various factors can affect the response and adverse drug reactions a patient may experience with anticancer therapy. When determining the optimal therapy, the health professional should carefully consider patient-specific factors, tumor-specific factors, and treatment goals.

PATIENT CARE PROCESS

Patient Care Process for Cancer



Collect
Assess
Plan
Implement
Follow-up: Monitor and Evaluate
Patient-Centered Care
Collaborate • Communicate • Document •

Collect

- Patient characteristics (eg, age, biological sex)
- Patient medical history (eg, comorbidities, prior anticancer therapies)
- Family history, social history, lifestyle factors, and dietary habits
- Current medications and allergies
- Objective data
    - Imaging (eg, PET scan, CT scan, MRI)
    - Tumor characteristics (eg, histology, mutations, stage)
    - Vital signs and laboratory values, including chemistries, organ function, CBC with differential, pregnancy status, hepatitis B serologies, and medication-specific assessments (eg, left ventricular ejection fraction for anthracyclines)
    - Physical exam
    - Pharmacogenomics, if applicable

Assess

- Performance status (see Table 149-1)
- Goals of care (eg, palliation)
- Treatment history (eg, type of treatment, response, tolerability)
- Desire for fertility preservation
- Immunization status

- Barriers to treatment (eg, transportation, insurance, compliance, health literacy)
- Role for nonmedication treatment measures (eg, radiation, surgery)
- Need for genetics counseling, if applicable

Plan

- Anticancer therapy regimen and supportive care
- Monitoring parameters (see Table 149-2)
- Patient education (eg, goals of care, drug-specific information, calendar for cyclic regimens, contraception requirements)
- Restaging timepoints to assess response
- Administration requirements (eg, central venous catheter)

Implement

- Administer immunizations prior to chemotherapy initiation, if possible
- Provide patient education regarding all elements of the treatment plan
- Obtain consent for anticancer therapy
- Schedule follow-up for response and toxicity assessments

Follow-Up: Monitor and Evaluate

- Assess adverse drug reactions and supportive care measures
- Assess patient adherence, if applicable
- Assess tumor response to treatment (eg, CT scan)
- Reevaluate goals of care
- Determine adherence to treatment plan

BEYOND THE BOOK

BEYOND THE BOOK

Patient Case

RM is a 64-year-old individual with newly diagnosed stage IV renal cell carcinoma (clear cell histology) who presents to clinic for initiation of anticancer treatment. Given her poor prognostic risk group, the oncologist recommends a vascular endothelial growth factor receptor (VEGFR) inhibitor and/or immunotherapy. Of the first-line therapy options provided in the National Comprehensive Cancer Network, or NCCN, guidelines, her insurance will cover the following: cabozantinib monotherapy; axitinib + pembrolizumab; cabozantinib + nivolumab; ipilimumab + nivolumab; and lenvatinib + pembrolizumab. The oncologist is requesting your assistance with treatment planning and implementation.

- PMH: HTN diagnosed 1.5 years ago, gastrointestinal perforation diagnosed 6 weeks ago, metastatic clear cell, renal cell carcinoma diagnosed 4 weeks ago

- Vitals: O_2 sat: 98% (0.98) RA; HR 82 bpm; BP 179/103 mm Hg; 37.4°C
- Labs:
    - Sodium 137 mEq/L (136–145 mEq/L [mmol/L])
    - Potassium 3.9 mEq/L (3.4–5.1 mEq/L [mmol/L])
    - Chloride 99 mEq/L (98–107 mEq/L [mmol/L])
    - Glucose 96 mg/dL (74–99 mg/dL) (5.3 mmol/L [4.1–5.5 mmol/L])
    - Albumin 4.1 (3.5–5.2 g/dL) (41 g/L [35–52 g/L])
    - Calcium 10.4 mg/dL (8.6–10.2 mg/dL) (2.60 mmol/L [2.15–2.55 mmol/L])
    - Magnesium 1.7 mg/dL (1.6–2.6 mg/dL) (0.70 mmol/L [0.66–1.07 mmol/L])
    - Creatinine 0.94 mg/dL (CrCl ~80 mL/min) (83 µmol/L [CrCl ~1.33 mL/s])
    - Phosphorous 2.8 mg/dL (2.5–4.5 mg/dL) (0.90 mmol/L [0.81–1.45 mmol/L])
    - ALT 28 U/L (0–33 U/L) (0.47 µkat/L [0–0.55 µkat/L])
    - AST 23 U/L (0–32 U/L) (0.38 µkat/L [0–0.53 µkat/L])
    - T Bili 0.02 mg/dL (0.00–1.2 mg/dL) (0.3 µmol/L [0–20.5 µmol/L])
    - Hgb 10.2 g/dL (11.2–15.7 g/dL) 102 g/L [112–157 g/L]; 6.33 mmol/L [6.95–9.74 mmol/L])
    - Platelets 225 × 10^3/mm^3 (173 × 10^3 – 369 × 10^3/mm^3) (225 × 10^9/L [173 × 10^9 – 369 × 10^9/L])
    - ANC 3.02 x 10^3/mm^3 (1.56 × 10^3– 6.13 × 10^3/mm^3) (3.02 × 10^9/L [1.56 × 10^9 – 6.13 × 10^9/L])
    - LDH 215 U/L (125--220 U/L) (3.58 µkat/L [2.08 –- 3.67 µkat/L])

Allergies: NKDA

Medication List: lisinopril 5 mg PO daily

Questions

Q1. Given all the first-line treatment options for clear cell renal cell carcinoma are covered by the patient's insurance, what treatment option would you recommend for RM at this time?

Q2. When counseling RM prior to treatment initiation, what adverse drug reactions should be discussed?

Q3. What monitoring parameters should be considered for the selected treatment regimen?

Answers

Q1. Given all the first-line treatment options for clear cell renal cell carcinoma are covered by the patient's insurance, what treatment option would you recommend for RM at this time?

A1: Nivolumab plus ipilimumab would be the best option for RM at this time. VEGFR inhibitors, including cabozantinib, axitinib, and lenvatinib, should be avoided due to her recent gastrointestinal perforation. Additionally, the patient's hypertension should be controlled before initiating treatment with a VEGFR inhibitor. Other comorbidities to consider when evaluating a patient for treatment with a VEGFR inhibitor include proteinuria, wound healing complications, bleeding, and embolism. RM has no autoimmune conditions or transplant history that would preclude the use of immune checkpoint inhibitors.

Q2. When counseling RM prior to treatment initiation, what adverse drug eactions should be discussed?

A2: Fatigue is a common adverse drug reaction associated with ipilimumab and nivolumab. Dermatologic reactions and endocrine dysfunction are also common. Less common but potentially serious autoimmune reactions such as colitis, pneumonitis, nephritis, hepatitis, myocarditis, and neurologic events can occur. Any organ system may be involved and immune-related adverse events (irAEs) may be fatal. Although less common, infusion-related reactions have been reported.

Q3. What monitoring parameters should be considered for the selected treatment regimen?

A3: Thyroid dysfunction, electrolytes, liver function, renal function, dermatologic evaluations, and gastrointestinal symptoms should be evaluated at baseline and monitored closely while on treatment. A CBC with differential may also be considered.

INTRODUCTION

Cancer is a group of many different diseases characterized by uncontrolled cellular growth, local tissue invasion, and distant metastases. It is the second leading cause of death in Americans. In the United States, nearly 1.9 million cases of cancer are projected to occur in 2022, with an estimated 600,000 deaths.[1] Figure 149-1 shows the estimated incidence of common cancers and cancer-related deaths. The most common cancers are prostate, breast, and lung cancer. The most common cause of cancer-related death in the United States is lung cancer, accounting for approximately 130,000 deaths each year. These cancers are discussed in further detail in subsequent chapters.

FIGURE 149-1

Estimated 2022 cancer incidences (top) and deaths (bottom) in the United States for males and females. *Estimates are rounded to the nearest 10 and exclude basal cell and squamous cell skin cancers and in situ carcinoma except urinary bladder. *(Reprinted, with permission, from Siegel RL, Miller KD, Fuchs HE, et al. Cancer Statistics. CA Cancer J Clin. 2022;72(1):7-33.)*

Health professionals treating patients with cancer should have a thorough understanding of the pharmacokinetic, pharmacodynamic, and pharmacogenomic properties of all available anticancer agents, in addition to the reported safety and efficacy of each agent in each cancer population. Health professionals should critically evaluate, summarize, and communicate the essential information to other health professionals, patients, and caregivers. This chapter defines the etiology, pathology, diagnosis, staging, and screening; introduces anticancer therapies and their related adverse drug reactions; and provides general information on how to administer systemic anticancer agents safely.

ETIOLOGY OF CANCER

Normal healthy cells are strictly regulated, with stimulatory and inhibitory signals in a delicate balance. For normal cells to become cancer cells, it is believed that a physical, chemical, or biological agent must damage the cell and cause a genetic and/or epigenetic alteration that is subsequently propagated during cell division. Cancer cells eventually acquire multiple alterations, and these alterations lead to uncontrolled proliferation, invasion, and metastases.

Carcinogenesis

① The mechanisms by which cancers occur are incompletely understood. A cancer is thought to develop from a cell in which the normal mechanisms that control cell growth and proliferation are altered. Current evidence supports the concept of carcinogenesis as a multistage process that is genetically regulated.[2,3] The first step in this process is *initiation*, which requires exposure of normal cells to carcinogens. These carcinogens produce genetic alterations that, if not repaired, result in irreversible cellular changes. The changed cell may subsequently have an altered response to their environment that provides a selective growth advantage and permits the development of a clonal population of cancer cells. During the second step, known as *promotion*, carcinogens or other factors alter the environment to favor growth of the altered cell population compared to normal cells. Promotion could be affected by chemoprevention strategies (strategies to lower cancer risk), including changes in lifestyle and diet. At some point, the altered cell becomes cancerous (*conversion* or *transformation*). Depending on the cancer, 5 to 20 years may elapse between the initiation and the development of a clinically detectable cancer. The final stage, called *progression*, involves further genetic alterations that lead to increased cell proliferation. The critical elements of this phase include invasion into local tissues and the development of metastases.

Substances that may act as carcinogens include a myriad of chemical, physical, and biologic agents. Chemical exposures may occur by occupational and environmental means or by lifestyle habits. Some chemicals associated with cancer include aniline dye, asbestos, and benzene. Aniline dye is a known cause of bladder cancer; benzene is a known cause of leukemia, and asbestos is a known cause of mesothelioma. As shown in Table 149-1, some medications and hormones used for therapeutic purposes are also classified as carcinogens.[4] Physical agents that act as carcinogens include ionizing radiation and ultraviolet light; radiation induces mutations by forming free radicals that damage deoxyribonucleic acid (DNA) and other cellular components. Biologic agents that are associated with certain cancers include natural compounds (ie, viruses) or pollutants. The Epstein-Barr virus may be an important factor in the initiation of Burkitt lymphoma. Similarly, infection with the human papilloma virus (HPV) is a cause of cervical and head-and-neck cancers. Hereditary factors, age, and gender may also contribute to the development of cancer.

TABLE 149-1

Selected Drugs and Hormones Known to Cause Cancer in Humans

Drug or Hormone	Type of Cancer
Alkylating agents (eg, chlorambucil, mechlorethamine, melphalan, procarbazine, and nitrosoureas)	Leukemia
Anabolic steroids	Liver
Anthracyclines (eg, doxorubicin)	Leukemia
Antiestrogens (tamoxifen)	Endometrium
Antithymocyte globulin	Lymphoma
BRAF inhibitors (dabrafenib, encorafenib, vemurafenib)	Primary malignancies
BTK inhibitors (acalabrutinib, ibrutinib, zanubrutinib)	Second primary malignancies
Cisplatin	Leukemia
Coal tars (topical)	Skin
Cobimetinib	Primary cutaneous malignancies
Elotuzumab	Second primary malignancies
Filgrastim	Leukemia
Isatuximab	Second primary malignancies
Lenalidomide	Second primary malignancies
PARP inhibitors (olaparib, niraparib, talazoparib)	MDS/AML
Pioglitazone	Bladder
Steroidal estrogens (estrogen replacement therapy, oral contraceptives)	Endometrium, breast, liver
Epipodophyllotoxins (etoposide)	Leukemia
Immunosuppressive drugs (cyclosporine, azathioprine)	Lymphoma, skin
Oxazaphosphorines (cyclophosphamide, ifosfamide)	Urinary bladder, leukemia
Tacrolimus	Lymphoma
Tazemetostat	Second malignancy
TNF-α inhibitors	Leukemia, skin
Voriconazole	Skin

FDA-approved package inserts. *Data from References 4,58,59.*

Genetic Alterations

In recent years, there has been marked progress in our understanding of the genetic changes that lead to the development of cancer.[2,3] Two types of genes play an important role in the development of cancer: oncogenes and tumor suppressor genes. Figure 149-2 illustrates the acquired capabilities of cancer cells that differ from normal cellular function.[5]

FIGURE 149-2

Functional capabilities acquired by cancer cells, including angiogenesis, self-proliferation, insensitivity to antigrowth signals and limitless growth potential, metastasis, and antiapoptotic effects. It is thought that most, if not all, cancer cells acquire these functions through a variety of mechanisms, including activation of oncogenes and mutations in tumor suppressor genes. *(Reprinted from Cuellar S, Haaf CM. Oncogenes

Oncogenes develop from normal genes, called proto-oncogenes. Proto-oncogenes are present in all cells and are essential regulators of normal cellular functions. Genetic alterations of the proto-oncogene through point mutation, chromosomal rearrangement, or gene amplification can activate the oncogene. Carcinogens may cause these genetic alterations (somatic mutations), or these alterations may be inherited (germline mutations). After activation, the oncogene produces either excessive amounts of the normal gene product or an abnormal gene product. The result is dysregulation of normal cell growth and proliferation, which imparts a distinct growth advantage to the cell and increases the probability of transformation. For example, the erythroblastic leukemia viral oncogene (*ErbB*) family members are oncogenes that mediate cell proliferation and differentiation through activation of intracellular signaling pathways. As an oncogene, the *ErbB* gene product is typically mutated, overexpressed, or amplified, resulting in excessive cellular proliferation, invasion, and metastasis in several cancers. Table 149-2 lists examples of oncogenes by their cellular function.

TABLE 149-2

Examples of Oncogenes and Tumor Suppressor Genes

Gene	Associated Human Cancer
Oncogenes	
ALK	Lung cancer, lymphomas, neuroblastoma, and ovarian cancer
BCR-ABL	ALL, CML
BCL-2	B-cell lymphomas, myeloid leukemia
BRAF	Colon cancer, lung cancer, melanoma, ovarian cancer, thyroid cancer
ERBB1	Colon cancer, glioblastoma multiforme, lung cancer
ERBB2	Breast cancer, gastric cancer, lung cancer
FLT3	AML, colorectal cancer
KIT (CD117)	Acute leukemia, GIST
MET	Lung cancer, colon cancer, melanoma, endometrial cancer
MYC	AML, breast cancer, lung cancer, pancreatic cancer, retinoblastoma, B- and T-cell lymphomas
PI3KCA	Lung cancer, ovarian cancer, breast cancer, lymphoma
RAS (NRAS, HRAS, KRAS)	Colon cancer, melanoma, ovarian cancer, thyroid cancer
ROS1	Lung cancer, cholangiocarcinoma
RET	Lung cancer, thyroid cancer
Tumor Suppressor Genes	
APC	Colon cancer, thymus cancer
BRCA1, BRCA2	Breast cancer, ovarian cancer, prostate cancer
MSH2, MLH1, PMS1, PMS2, MSH6	Colon cancer
NF1, NF2	Leukemias, melanoma
TP53	Multiple cancers
PTEN	Lung cancer, ovarian cancer
RB1	Bladder cancer, retinoblastoma, sarcoma
VHL	Renal cell cancer

Tumor Suppressor Genes

Tumor suppressor genes regulate and inhibit inappropriate cellular growth and proliferation.[2] Genetic alterations result in loss of control over normal cell growth. *Retinoblastoma* 1 and *TP53* are examples of tumor suppressor genes. Mutation of *TP53* is one of the most common genetic alterations associated with cancer. The normal gene product of *TP53* is responsible for negative regulation of the cell cycle (ie, a series of cellular events that lead to the division and duplication of a cell), allowing the cell cycle to halt for repairs, corrections, and responses to other external signals. Inactivation of *TP53* following a genetic alteration removes this checkpoint, allowing genetic alterations to accumulate within a cell. Mutation of *TP53* is linked to a variety of cancers. For example, a germline mutation in which an individual has only one functional copy of *TP53* is associated with Li-Fraumeni syndrome, a syndrome characterized by multiple cancers by early adulthood. Another important function of *TP53* may be modulation of cytotoxic drug effects; loss of *TP53* is associated with anticancer drug resistance.

DNA Repair Genes

Another important type of gene that plays a role in cancer development is the DNA repair gene. Their normal function is to repair DNA damaged by environmental factors or errors in DNA that occur during replication.[2] If not corrected, these errors can result in alterations that activate oncogenes or inactivate tumor suppressor genes. Subsequently, more genetic alterations accumulate within a cell, and the risk for transformation increases for the altered cell population. Specifically, DNA repair genes can affect mismatch repair, single-strand break repair, and double-strand break repair. For example, poly ADP ribose polymerase (PARP) is a family of proteins responsible for DNA repair and programmed cell death by affecting multiple repair mechanisms.[6] PARP1 is a member of the PARP family that plays a role in repairing single-strand DNA breaks. Deficiencies in DNA repair genes have been discovered in breast, colon, and ovarian cancers.

Accumulation of Genetic Alterations

It has become evident that a single genetic alteration is probably insufficient to initiate cancer. Most cancers acquire multiple somatic genetic alterations; some alterations may make no contribution to the development of cancer (eg, passenger mutations), while other alterations likely support the ongoing survival of cancer (eg, driver mutations). Scientists postulate that combinations of alterations are required for carcinogenesis and that the next generation of cells inherits each alteration. Thus, several detectable genetic alterations may be present in cancer. Although early alterations are found in premalignant lesions and established cancers, later alterations are found only in established cancer. This theory of sequential genetic alteration has been demonstrated in colon cancer. In colon cancer, the initial genetic alteration is believed to be loss of the *APC, or adenomatous polyposis coli* gene, which results in the formation of a small benign polyp (ie, abnormal tissue growth in a mucus membrane). An oncogenic mutation of ras genes is often the next step, leading to enlargement of the polyp. Loss of function of DNA mismatch repair enzymes may occur at many points during the transformation. Loss of *TP53* and another gene, believed to be the *deleted in colorectal cancer, or DCC,* gene, completes the transformation. Loss of *TP53* may be a late event in the development and progression of colon cancer and other cancers.

Four genes have been associated with DNA mismatch repair: *mutL homologue 1, mutS homologue 2, mutS homologue 6*, and *postmeiotic segregation increased 2*. When one or more of these proteins is mutated or missing, mistakes made during DNA replication may not be recognized or repaired. As a result, the tumor cell has a higher frequency of mutations known as mismatch repair deficient (dMMR). Tumors with a defective mismatch repair system may contain thousands of somatic mutations.[7] When a high number of these mutations accumulate within microsatellites (short repeating sequences of DNA), the tumor is characterized as microsatellite instability-high (MSI-H). As discussed later in the chapter, dMMR and MSI-H tumors are more susceptible to immune checkpoint inhibitors.

Epigenetic Alterations

Epigenetics refers to changes in gene expression that occur without altering the DNA sequence. The two most common mechanisms of epigenetic regulation include methylation and histone modification. DNA methylation commonly occurs at CpG dinucleotides (or islands) and is catalyzed by DNA methyltransferases (DNMTs). Histones are basic proteins associated with DNA in the nucleosome. These proteins may be modified by acetylation, methylation, or phosphorylation on their N-terminal tail. These modifications play a role in transcriptional regulation. For example, histone deacetylases (HDAC) repress transcription, and histone acetylases activate transcription. Epigenetic changes may be involved in the development of cancer by either priming the cell or making it susceptible to genetic alterations associated with the development of cancer. For example, hypermethylation at CpG dinucleotides found near tumor suppressor genes can switch these genes off and promote cancer development. Anticancer agents, identified as inhibitors of DNMT or HDAC, target these modifications. Figure 149-3 shows the effects of these inhibitors on methylation, chromatin formation, and transcription.

FIGURE 149-3

Epigenetic regulation of gene expression in cancer cells. CpG islands within the promoter and enhancer regions of the gene are methylated, resulting in the complexes with HDAC activity. Chromatin is in a condensed conformation that inhibits transcription (upper figure). Inhibitors of DNMT with inhibitors of HDAC confer a chromatin structure that allows transcription (lower figure). *(Reproduced, with permission, from Longo DL. Cancer cell biology and angiogenesis. An oncometabolite is a metabolite whose abnormal accumulation may result in epigenetic dysregulation and carcinogenesis. Isocitrate dehydrogenase (IDH) 1 and 2 are enzymes involved in cellular metabolism through the conversion of isocitrate to alpha-ketoglutarate (αKG).[8] Mutations in *IDH1* and *IDH2* have been identified in gliomas and acute myeloid leukemia (AML) and result in the conversion of αKG to D-2-hydroxyglutarate. Elevated levels of D-2-hydroxyglutarate, an oncometabolite, inhibit αKG-dependent histone and DNA demethylases, which have been associated with impaired cellular differentiation. Anticancer agents have been developed to inhibit the mutant variants of IDH1 and 2 enzymes, thereby restoring myeloid differentiation.

PATHOLOGY OF CANCER

② Cancer cells demonstrate several characteristics that differentiate them from normal cells. These traits include uncontrolled proliferation in which the cell cycle is no longer strictly regulated. Genetic alterations permit activation of multiple oncogenes and suppression of various tumor suppressor genes, releasing the cancer cells from the strict regulation observed with healthy cells. The cancer cells subsequently undergo multiple cell divisions, allowing the tumor size to increase exponentially. Cancer cells also resist programmed cell death by inhibiting apoptosis and senescence (aging). Lastly, cancer cells grow new blood vessels, invade new local tissue, and spread to distant sites.

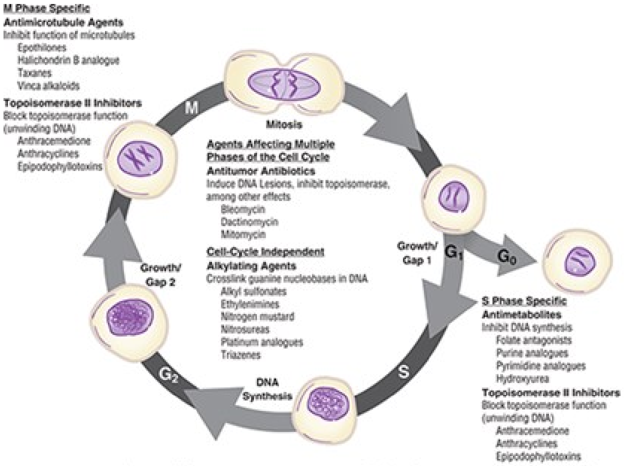
Cell Cycle

The cell cycle incorporates a series of events by which normal and cancer cells divide and make new cells. This process is strictly regulated in healthy cells. Oncogenes and tumor suppressor genes provide the stimulatory and inhibitory signals that regulate the cell cycle. These signals converge on a molecular system in the nucleus known as the cell-cycle clock. The function of the clock in healthy cells is to integrate the signal input and determine if the cell cycle should proceed. The clock is composed of a series of interacting proteins, the most important of which are cyclins and cyclin-dependent kinases (CDKs). Cyclins and CDKs promote entry into the cell cycle and are overexpressed in several cancers. CDK inhibitors have been identified as important negative regulators of the cell cycle.

The cell cycle proceeds from one cell division to the next. The cycle involves five phases: DNA replication (S phase), cell division (M phase), two resting phases (G_1 and G_2), and a nondividing state (G_0 phase). In the first resting phase, G_1, the cell grows in size and decides to commit to the cell cycle or remain in a resting state. If the cell is normal, the cell will move into the S phase to synthesize its DNA. Next, the cell enters the second resting phase, G_2, in which the cell prepares to divide. In the M phase, the cell enters mitosis and yields two daughter cells. If the cell is not healthy, the cell can stop dividing and initiate apoptosis. Figure 149-4 depicts the cell cycle and the phases of activity for some chemotherapy agents.

FIGURE 149-4

Cell-cycle activity for chemotherapy. Cell-cycle phase-specific chemotherapy is most active during a particular phase. Cell-cycle phase-nonspecific chemotherapy may have activity in more than one phase. In many cases, it is likely that chemotherapy cytotoxicity involves multiple intracellular sites of action and may not be linked to specific cell-cycle events.



M Phase Specific
Antimicrotubule Agents
Inhibit function of microtubules
Epothilones
Halichondrin B analogue
Taxanes
Vinca alkaloids

Four checkpoints exist within the cell cycle, one in each phase of the cell cycle, and serve as quality control checkpoints. The cell will not proceed to the next phase unless all requirements for the current phase are met. Complexes of cyclin and CDK regulate these checkpoints. These complexes lead to the activation of other proteins that are responsible for the specific events of each phase of the cell cycle. The first checkpoint is called the restriction site. *Retinoblastoma* complexed to a transcription factor called E2F controls the restriction site. The presence of this complex prevents cell-cycle progression. A cell can proceed beyond the G_1 restriction site and continue into the S phase when cyclin–CDK complexes phosphorylate *Retinoblastoma* and target it for degradation. A cell may alternatively withdraw into the G_0 phase in the presence of antimitogenic or the absence of mitogenic factors.

Defense Systems

When the normal regulatory mechanisms for cell growth fail, backup defense systems may be activated. The secondary defenses include apoptosis (programmed cell death or suicide) and cellular senescence. Apoptosis is a normal mechanism of cell death required for tissue homeostasis. This process is regulated by oncogenes and tumor suppressor genes and is also a mechanism of cell death after exposure to cytotoxins. Overexpression of oncogenes responsible for apoptosis may produce an “immortal” cell, which has increased potential for malignancy. For example, *B-cell lymphoma 2* (*BCL-2*) is normally located on chromosome 18, but it may be translocated to chromosome 14 in proximity to the immunoglobulin heavy chain gene. This translocation leads to overexpression of *BCL-2* in lymphoid malignancies, which decreases apoptosis and confers a survival advantage. As another example, loss of *TP53* disrupts normal apoptotic pathways, imparting a survival advantage. Apoptosis may also play an important role as a mechanism of inherent resistance to some chemotherapy agents.

Cellular senescence is another important defense mechanism.[2] Laboratory studies demonstrate that after a cell population has undergone a preset number of doublings, growth stops and the cells die. This is known as senescence, a process that is regulated by telomeres. Telomeres are the DNA segments or caps at the ends of chromosomes. They are responsible for protecting the end of the DNA from damage. With each replication, the length of the telomeres is shortened. After the telomeres are shortened to a critical length, senescence is triggered. In this way, telomeres tally and limit the number of cell doublings. In cancer cells, the function of telomeres is overcome by overexpression of an enzyme known as telomerase. Telomerase replaces the portion of the telomeres lost with each cell division, thereby avoiding senescence and permitting an infinite number of cell doublings.

Immune Evasion

Immunosurveillance, a key feature of the host immune system, is recognizing and eliminating abnormal cells, including malignant cells. Antitumor immunity depends on T-cell identification of tumor antigens: a process regulated in part by various receptor-ligand interactions. Cytotoxic T-lymphocyte–associated antigen-4 (CTLA-4) and programmed death-1 (PD-1) are inhibitory receptors expressed on activated T-cells that serve as immune checkpoints. Checkpoints are critical in maintaining self-tolerance and preventing autoimmunity. When these T-cell receptors bind to their respective ligands on tumor cells, B7-1 and PD-ligand-1 (PD-L1), T-cell down-regulation occurs and the tumor is able to evade immunosurveillance. These ligands are overexpressed on multiple types of tumors, and this process represents one of the multiple mechanisms that tumors evade immune elimination. Immune checkpoint inhibitors block the receptor-ligand interactions, reverse the immune down-regulation, and allow for tumor cell elimination.

Cancer Growth

The study of cancer growth forms the foundation for many of the basic principles of modern chemotherapy. The growth of cancerous tumors is based on Gompertzian kinetics (see Fig. 149-5).[2] Gompertz was an insurance actuary who described the relationship between age and expected death. This mathematical model also approximates cancer cell proliferation. In the early stages, cancer growth is exponential, which means that cancer takes a constant amount of time to double its size. During this early phase, most cancer cells are actively dividing. This population of cells is called the growth fraction. The doubling time, or time required for cancer to double in size, is very short. Because cytotoxic chemotherapy agents typically have a greater effect on rapidly dividing cells, cancers are most sensitive to their effects when the cancer is small, and the growth fraction is high. As cancer grows, the doubling time is slowed. The growth fraction decreases, probably owing to cancer outgrowing its blood and nutrient supply or the inability of blood and nutrients to diffuse throughout the mass. Wide variability exists in measured doubling times for different cancers. The doubling time of most solid tumors is about 2 to 3 months, but some cancers have doubling times of only days (eg, aggressive non-Hodgkin lymphoma [NHL]).[9]

FIGURE 149-5

Gompertzian kinetics tumor-growth curve: relationship to symptoms, diagnosis, and various treatment regimens. *(Reproduced, with permission, from Buick RN. Cellular basis of chemotherapy. In: Dorr RT, Von Hoff DD, eds. Cancer Chemotherapy Handbook. 2nd ed. New York, NY: Appleton & Lange/McGraw Hill; 1994:3-14.)*

Tumor burden impacts diagnosis and treatment (see Fig. 149-5). It takes about 10^9 cancer cells (1 g mass, 1 cm in diameter) for cancer to be clinically detectable by palpation or radiography. A cancer of this size has likely undergone about 30 doublings in cell number. It only takes 10 additional doublings for this 1 g mass to reach 1 kg in size. Cancer possessing 10^{12} cells (1 kg mass) is considered lethal. Thus, a cancer is clinically undetectable for most of its life span. Tumor burden also impacts treatment. The cell kill hypothesis states that a certain percentage of cells will be killed with each course of cytotoxic chemotherapy. For example, if cancer consists of 1,000 cells and the first treatment kills 90% of the cells, then 10% or 100 cells remain. The second treatment kills another 90% of cells, and again only 10% or 10 cells remain. According to this hypothesis, the tumor burden will never reach zero. Cancers consisting of less than 10^4 cells are believed to be small enough for elimination by host factors, including immunosurveillance. The limitations of this theory are that it assumes all cancers are equally responsive to treatment and that resistance to anticancer agents and the development of metastases do not occur.[2]

Invasion and Metastasis

As cancer grows, cancer cells break away or shed from the primary site to invade surrounding tissue and metastasize to distant sites. Metastatic disease is associated with a poorer prognosis and shortened survival compared to earlier disease. The cancer cells invade adjacent tissue or metastasize to distant sites by hematogenous or lymphatic spread, but not all shedded cells result in a metastatic lesion. The shed cells must first find an environment suitable for growth. The onset and time course for metastasis development depends largely on the individual cancer, as illustrated by the diverse patterns of metastasis observed for different cancers. Breast cancer, for example, tends to metastasize very early. Prostate cancer commonly metastasizes to bone, and colon cancer commonly metastasizes to the liver. Other less common modes of disease spread include dissemination via cerebrospinal fluid and transabdominal spread within the peritoneal cavity.

For a cancer cell to break away from the primary tumor site, the shed cell and surrounding host tissue must first secrete substances that stimulate angiogenesis. The shed cells must then detach from the primary tumor by expressing proteins that degrade the extracellular matrix, such as matrix metalloproteases, and invade surrounding blood and lymph vessels. The cells must then attach to the vascular endothelium. The cells may proliferate within the lumen of the vessel but most commonly extravasate into the surrounding tissue. The local microenvironment may provide growth factors that can serve as fertilizer to potentiate the development of a metastatic site. At every step, the potential metastatic cell must fight the host immune system. Finally, the metastasis must again initiate angiogenesis to ensure continued growth and proliferation.

Angiogenesis is the development of new blood vessels. This process becomes unregulated in several cancers and supports growth, invasion, and metastasis. Angiogenesis is regulated by pro- and antiangiogenic growth factors, which are released in response to hypoxia and other stresses to the cell. Proangiogenic growth factors include vascular endothelial growth factor (VEGF), fibroblast growth factor, platelet-derived growth factor (PDGF), and tumor necrosis factor-alpha (TNF-α). Antiangiogenic growth factors include interleukin-12, or IL-12, interferon, and tissue inhibitors of metalloproteinases. The best-studied proangiogenic factor is VEGF, whose elevated levels have been associated with a poor prognosis and an increased risk of metastases in many cancers, including breast cancer, non-small cell lung cancer (NSCLC), ovarian cancer, and colon cancer. Similar to other growth factors, VEGF binds to specific receptors located on the extracellular domain: VEGF-receptor (VEGFR)-1, -2, and -3. VEGFR1 and VEGFR2 are expressed primarily in endothelial cells and some cancer cells and mediate the biologic effects of VEGF. Each of the receptors induces a different signal transduction pathway. These pathways eventually result in the generation of proteases necessary for the breakdown of the extracellular matrix. Inhibiting the development of new blood vessels can limit or prevent tumor growth.

DIAGNOSIS OF CANCER

Tumors may be either benign or malignant. Benign tumors are noncancerous growths that are often encapsulated, localized, and indolent. Benign tumors are named for the cell or tissue of origin, followed by the suffix-oma. The tumor cells resemble the cells from which they developed. These masses seldom metastasize and rarely recur after being removed. In contrast to benign tumors, malignant tumors invade and destroy the surrounding tissue. The cancer cells are genetically unstable, and loss of normal cell architecture results in cells that are atypical of their tissue or cell of origin. These cells lose the ability to perform their usual functions. This loss of structure and function is called anaplasia. Cancers tend to metastasize, and consequently, recurrences are common after removal or destruction of the primary tumor. Cancers arising from epithelial cells are called carcinomas, and those arising from muscle or connective tissue are called sarcomas. Table 149-3 lists common nomenclature by tissue type.[10]

TABLE 149-3

Tumor Classification by Tissue Type

Tissue of Origin	Benign	Malignant
Epithelial Tissues		
Stratified squamous	Papilloma	Carcinoma (squamous, epidermoid)
Glandular tissue	Adenoma	Adenocarcinoma
Connective tissue		
Fibrous tissue	Fibroma	Fibrosarcoma
Bone	Osteoma	Osteosarcoma
Fat	Lipoma	Liposarcoma
Cartilage	Chondroma	Chondrosarcoma
Muscle		
Smooth muscle	Leiomyoma	Leiomyosarcoma
Striated muscle	Rhabdomyoma	Rhabdomyosarcoma
Blood and lymphoid cells		
	“Myeloproliferative disorders”	Leukemias
Lymphoid tissue	Plasmacytosis	Plasmacytoma; multiple myeloma; Hodgkin and NHL
Neural tissue		
Glial tissue	“Benign” gliomas	Glioblastoma multiforme; astrocytoma
Nerve sheath	Neurofibroma	Neurofibrosarcoma
Meninges	Meningioma	Malignant meningioma
Other cells		
Pigment-producing cells	Nevus	Melanoma

Screening

3 Because cancers are most curable before they metastasize, early detection and treatment have obvious potential benefits. Cancer screening programs are designed to detect cancers in individuals who have not yet developed symptoms. Still screening is only available for a few cancers, such as colon, prostate, breast, lung, and cervical cancers. Available screening tools include a cytology test, the Papanicolaou, or Pap, smear test for cervical cancer, and mammography for breast cancer. Limitations of the available screening tests include false-negative test results (related to the sensitivity of the test), false-positive test results (related to the specificity), and overdiagnosis (true positives not likely to become clinically significant). For example, most abnormal test results identified by screening mammography are false-positive, although the specificity of a mammogram exceeds 90%. For most cancers, a lack of effective screening method and inaccessible anatomic site limits the potential impact of a screening program. Public education on the early warning signs of common cancers is therefore extremely important for facilitating early detection. The American Cancer Society and other organizations publish guidelines for routine screening examinations (see Table 149-4).[11,12]

TABLE 149-4

American Cancer Society Screening Guidelines for Early Detection of Cancer in Average-Risk Asymptomatic Individuals

Cancer	Population	Age (years)	Test or Procedure	Frequency
Breast	Women	40-44	Mammography	Every year, optional
		45-54		Every year
		≥ 55		Every 1-2 years; depending on life expectancy
Cervical	Individuals with a cervix	25-65	Primary HPV test alone[a]	Every 5 years (preferred)
			Co-testing (cytology [Papanicolaou, or Pap, smear test] and HPV test) every 5 years	Every 5 years; acceptable if access to primary HPV testing is not available
			Cytology (Papanicolaou, or Pap, smear test) alone	Every 3 years; acceptable if access to primary HPV testing is not available
		> 65	Options as above	Options as above should be continued until criteria for cessation are met[b]
Colorectal	All	45-75	Fecal immunochemical test	Annual
			High-sensitivity guaiac-based fecal occult blood test	Annual
			Multitarget stool DNA test	Every 3 years
			CT colonography	Every 5 years
			Flexible sigmoidoscopy	Every 5 years
			Colonoscopy	Every 10 years
		76-85	Options as above	Options as above; depending on patient history, preferences, and life expectancy
Lung	Current or former smokers, ≥ 30-pack-year history	55-74	Low-dose helical CT	Annual[c]
Prostate	Individuals with a prostate	≥ 50	Prostate-specific antigen test with or without digital rectal examination	Option if at least a 10-year life expectancy to make informed decision with their healthcare provider whether to be screened

[a] Use an FDA-approved HPV test for primary screening.

[b] Adequate negative prior screening is two consecutive negative primary HPV tests, or two negative cotests, or three negative cytology tests within the last 10 years, with the most recent occurring within the last 3-5 years.

[c] In adults who currently smoke or have quit within the last 15 years and have at least a 30-pack-year history and receive evidence-based smoking cessation counseling if they are current smokers and have undergone a process of informed/shared decision making that included information about the potential benefits, limitations, and harms of screening with low-dose CT and have access to a high-volume, high-quality lung cancer screening and treatment center.

Data from References 11,12.

Clinical Presentation

④ The presenting signs and symptoms vary widely and depend on the type of cancer. The presentation in adults may include any of the seven warning signs listed in Table 149-5, as well as headaches, weight loss, chronic pain, fatigue, or anorexia.[13] The warning signs of cancer in pediatrics are different and reflect the cancers more common in this population (see Table 149-6). The definitive diagnosis of cancer relies on procuring a tissue sample and pathologic assessment of this sample. This sample can be obtained by numerous methods, including an excisional, core, or needle aspiration biopsy. A tissue diagnosis is essential because many benign tumors can masquerade as cancers and most tumors are not cancer. Depending on the tumor type, the diagnosis may include evaluating genetic alterations such as hormone receptor status in breast cancer or epidermal growth factor receptor (EGFR) status in NSCLC. Multiple companion or complementary tests are available and are indicated to detect a select mutation associated with a specific tumor type or identify hundreds of genetic mutations in any solid tumor.

TABLE 149-5

Cancer's Seven Warning Signs

Change in bowel or bladder habits
A sore that does not heal
Unusual bleeding or discharge
Thickening or lump in the breast or elsewhere
Indigestion or difficulty in swallowing
Obvious change in wart or mole
Nagging cough or hoarseness
If YOU have a warning signal, see your doctor!

Data from Reference 13.

TABLE 149-6

Cancer's Warning Signs in Children

Continued, unexplained weight loss
Headaches with vomiting in the morning
Increased swelling or persistent pain in bones or joints
Lump or mass in abdomen, neck, or elsewhere
Development of a whitish appearance in the pupil of the eye
Recurrent fevers not caused by infections
Excessive bruising or bleeding
Noticeable paleness or prolonged tiredness

Staging

Following a pathologic diagnosis, cancers should be staged to determine the extent of the disease (ie, tumor location and size) before starting treatment. Staging provides information on prognosis and guides treatment selection. A staging workup may involve physical examination, biopsy, imaging tests (ie, computed tomography [CT] scans, magnetic resonance imaging [MRI], and positron emission tomography [PET] scans), and laboratory tests. The laboratory tests may include tumor markers, antigens, or other substances produced by cancer. However, tumor markers are often nonspecific and may be elevated in many different cancers or patients with nonmalignant conditions. As a result, tumor markers are generally more useful for monitoring response and detecting recurrence than diagnostic tools. For example, human chorionic gonadotropin, or hCG, and alpha-fetoprotein, or AFP, in testicular cancer or prostate-specific antigen, or PSA, in prostate cancer are useful markers to monitor response or recurrence. After starting treatment, the staging workup is usually repeated at regular intervals to evaluate the effectiveness of the treatment.

The most common staging system for solid tumors is the TNM system that describes the tumor (T), nodes (N), and metastases (M). A numerical value is assigned to each letter to indicate the size or extent of disease. The T describes the size of the primary tumor and spread to adjacent tissues; the N specifies the size, location, and number of regional lymph nodes affected by cancer; and the M describes the presence or absence of metastases. Each letter is followed by an Arabic number that uniquely describes that tumor, node, or metastases. After the individual T, N, and M are determined, their values are combined to provide an overall stage identified using Roman numerals ranging from stage I to stage IV. For example, stage $T_3N_1M_0$, which describes a moderate-to-large primary mass with regional lymph node involvement and no distant metastases, is typically a stage III cancer. This simplified staging system allows healthcare professionals to identify the extent of disease easily. For example, stage I usually indicates localized cancer, stages II and III typically indicate local and regional disease, and stage IV typically indicates distant metastases. The criteria for classifying disease extent are quite specific for each different cancer. Alternative staging systems are used in clinical practice for leukemias and lymphomas, as discussed in subsequent chapters.

TREATMENT MODALITIES

Three main modalities are used to treat cancer: surgery, radiation, and systemic anticancer agents. These modalities may be used alone but are typically given sequentially or concurrently to treat a specific cancer. The timing of the different modalities relative to one another is based on the outcomes of a clinical trial.

Surgery is the oldest treatment modality, and it plays a major role in diagnosis and treatment. It may be curative if the primary cancer has not metastasized. Surgery remains the treatment of choice for most early stage cancers, such as breast and colon cancers. Surgery typically involves the removal of the primary tumor and adjacent lymph nodes. This modality may also be used to remove isolated metastases and relieve symptoms associated with metastatic disease. For example, hepatic metastases may be removed for patients with colon cancer.

Radiation therapy can be used alone for localized cancer or cancer that may encompass a single radiation field. It was first used to treat cancer in the late 1800s and remains a mainstay of treatment for some cancers. Radiation therapy may also be used to alleviate symptoms associated with vena cava syndrome, bone metastases, spinal cord compression, and brain tumors. This modality typically damages normal tissue surrounding the cancer, but the normal tissue typically repairs itself more readily than the cancer cells. Several different types of radiation therapy are available, including external beam radiation therapy, stereotactic radiation, brachytherapy, and radioisotopes. Both early and late toxicities associated with radiation therapy are dependent on the organs within the radiation field. For example, mucositis is commonly observed in patients receiving radiation for head-and-neck cancer. Secondary cancers are a devastating late toxicity that can occur following radiation therapy.

Systemic anticancer agents include chemotherapy, targeted therapy, and immunotherapy. Hormonal therapy is used for the treatment of cancer and is discussed in other chapters. Multiple radiopharmaceuticals are also now available. In general, systemic anticancer agents are developed to destroy cancer cells while minimizing effects on healthy cells. Specific agents will be discussed later in this chapter.

Combined Modality Treatment

As stated earlier in the chapter, a cancer may be treated with multiple modalities. For example, systemic anticancer agents are often administered to patients with local disease (ie, early stage) following surgery or radiation therapy. Because many patients with local disease have undetectable metastatic disease (ie, micrometastases) at diagnosis, localized anticancer treatment alone may fail to eliminate the cancer completely. *Adjuvant* therapy is systemic therapy administered to eradicate micrometastatic disease after surgery or radiation. The goal of adjuvant therapy is to reduce recurrence rates and prolong long-term survival. Thus, adjuvant therapy is given to patients with potentially curable cancers who have no clinically detectable disease after surgery or radiation. Because adjuvant therapy is given when the cancer is undetectable (ie, no measurable disease), its effectiveness is evaluated by recurrence rates and survival. *Neoadjuvant* (ie, preoperative or preradiation) therapy may be given to patients before surgery or radiation therapy to reduce tumor burden and destroy micrometastases. For example, neoadjuvant therapy has been given to patients with breast cancer to reduce the primary tumor size and allow for a less invasive surgical procedure.

The management of hematologic malignancies typically involves systemic anticancer therapies and radiation therapy since these cancers are systemic diseases that cannot be effectively treated with localized modalities. Systemic therapy that is administered to eradicate the cancer cells is called *induction* therapy. When a complete remission (the disappearance of all signs of cancer) is documented, postremission, or *consolidation*, therapy is administered. These therapies are designed to eradicate any remaining disease, similar to adjuvant therapy for solid tumors, and can include systemic therapy, a hematopoietic stem cell transplant (HSCT), or radiation therapy. *Maintenance* therapy is sometimes administered after consolidation therapy. The goal of this therapy is to prevent cancer from recurring or to maintain a response. Not all treatment phases are employed for all hematologic malignancies.

Goals of Care

The goals of care depend on the cancer stage and patient factors, such as comorbidities. When an anticancer agent is administered to patients with local or regional disease, the treatment (eg, adjuvant therapy) is often administered to cure the patient and may be labeled as *curative* therapy. When cancer has metastasized to distant sites, a cure is usually not possible, with rare exceptions, including testicular cancer. Anticancer therapy may be administered to patients with metastatic disease to slow cancer progression and prolong survival by months to years. If anticancer therapy is given to patients with the goal of reducing symptoms, the treatment is often called *palliative* therapy.

SYSTEMIC THERAPY

Chemotherapy

Chemotherapy was first administered in 1941 when Goodman and Gilman gave nitrogen mustard to patients with lymphoma. As discussed later in the chapter, a chemotherapy agent is typically given as part of a combination regimen, in which multiple anticancer agents with different mechanisms of action and toxicities are given together. Most chemotherapy agents target rapidly proliferating cells (both normal and cancer cells), and these agents might act at one or more phases of the cell cycle. A chemotherapy agent that demonstrates major activity in a particular phase of the cell cycle is known as a cell-cycle phase-specific agent. For example, antimetabolites exert their effect during the S phase. Cell-cycle phase-specific agents may be less active in other phases of the cell cycle. A cell-cycle phase-nonspecific agent has significant activity in multiple phases. Alkylating agents, such as nitrogen mustards, are examples of cell-cycle phase-nonspecific agents. Despite this classification, it is believed that most chemotherapy agents provide cytotoxic effects following interactions with other intracellular activities, not just specific cell-cycle events. Knowledge of cell-cycle specificity has been used to optimize treatment schedules. For example, a cell-cycle phase-specific chemotherapy agent is typically administered as a continuous infusion or in multiple repeated fractions to maximize the number of cancer cells in the sensitive cell-cycle phase. Thus, a cell-cycle phase-specific chemotherapy agent is also termed “schedule dependent.” In contrast, cell-cycle phase-nonspecific chemotherapy is active in many phases, and consequently, these agents are not schedule dependent. The activity of these chemotherapy agents depends on the dose, so these chemotherapies are termed “dose-dependent.” Chemotherapy agents are typically given in a defined repeating schedule called a cycle. The cycle length typically depends on the toxicities associated with the chemotherapy agent, such that sufficient time elapses between doses to allow a patient to adequately recover from a serious adverse drug reaction (eg, neutropenia). The number of cycles depends, in part, on the treatment goals. The number of cycles is typically defined by prior clinical trials for early stage disease. In contrast, the number of cycles is generally determined by individualized treatment response and tolerability for locally advanced or metastatic disease.

Targeted Agents

Targeted anticancer agents, including small-molecule inhibitors and mAbs, stop cancer progression by blocking aberrant intracellular signaling pathways that govern cell responses, movement, and division. Some of these agents can cause cancer cell death by inducing apoptosis or stimulating the immune system to destroy the cancer cells.

The first small-molecular targeted agent was developed in the late 1980s. Small-molecule targeted agents have a low molecular weight (less than 1,000 Da) and have been specifically designed to interfere with intracellular signaling pathways. These agents are typically given orally once or twice daily until disease progression or unacceptable toxicity occurs. Since resistance commonly develops with small-molecule targeted agents, they may be administered concurrently with other anticancer agents.

Similar to small-molecule targeted agents, most mAbs are administered with other anticancer treatments. Both mAbs and targeted agents have been developed to interfere with intracellular signaling. Although small-molecule targeted agents typically inhibit intracellular kinases, mAbs target the extracellular receptors or their natural ligands and prevent ligand binding to the receptor. The net effect of both strategies is to interfere with intracellular signal transduction and decrease cell proliferation (see Fig. 149-6). Some common receptors and pathways affected by available small-molecule targeted agents and mAbs include ErbB2 family, mitogen-activated protein kinase (MAPK) pathway, and phosphatidylinositide 3-kinase (PI3K) pathway.

FIGURE 149-6

Common intracellular signaling pathways and targeted therapies that inhibit these pathways. Activation of the PI3K-AKT pathway, the MAPK pathway, or the JAK/STAT pathway leads to downstream signaling and ultimately cell proliferation and survival. (*Image created with BioRender.)*

The ErbB family of receptors contains four known members: ErbB1 (also known as EGFR), ErbB2 (human EGFR 2 [HER2]), ErbB3, and ErbB4. EGFR and HER2 are overexpressed in several cancers, including breast, lung, gastric, and colon cancers. The roles of the other receptors in cancer growth and proliferation are still under investigation. Members of this family are inactive by themselves and must form a dimer (a molecule composed of two subunits) either with a member of the same family (homodimer) or with a member of a different ErbB family (heterodimer). Dimerization of the receptor leads to kinase phosphorylation and subsequent activation of downstream pathways required to activate signal transduction and cell growth.

Well-described intracellular signaling pathways include PI3K, Janus kinase–signal transducers (JAK) and activators of transcription (STAT), and MAPK. When these pathways are activated, they promote cell proliferation and survival. These pathways consist of a chain of proteins that ultimately communicate a signal from a cell surface receptor to the DNA found in the nucleus. A protein within a signaling pathway communicates by adding a phosphate group to its neighboring protein; the phosphate groups act as an “on” or “off” switch for the pathway. In cancer, a mutated protein permits the pathway to remain in the “on” or “off” position. The downstream effectors of these pathways also initiate cell-cycle progression by promoting the expression of cyclins and repressing the expression of CDK inhibitors.

The MAPK signaling pathway regulates many fundamental cellular processes, including cell differentiation, proliferation, and senescence. These pathways relay the intracellular signals through a series of ras, raf, MEK (MAPK-extracellular signal-regulated kinase), and extracellular signal-regulated kinase (ERK) proteins that subsequently phosphorylate and regulate nuclear and cytoplasmic structures. Some of these proteins are commonly altered in pancreatic, melanoma, colorectal, hepatocellular, and other solid tumors.

The PI3K signaling pathway also regulates cell proliferation, growth, survival, and mobility. PI3K becomes activated in response to growth hormones. It ultimately activates protein kinase B (known as AKT), a serine-threonine kinase that serves as a master switch for the cell-cycle progression. Fully activated protein kinase B translocates to the nucleus, inhibiting proapoptotic signals and activating antiapoptotic substrates. It can also phosphorylate mammalian target of rapamycin (mTOR). After being activated, mTOR stimulates protein synthesis by phosphorylating translation regulators. mTOR also contributes to protein degradation and angiogenesis. Phosphatase and tensin homolog, or *PTEN* is a tumor suppressor gene that blocks intracellular signaling through this pathway and is frequently inactivated in several solid tumors.

The JAK-STAT signaling pathway helps regulate the immune system. This pathway contains three main components: extracellular receptors, JAKs, and STAT. The pathway is initiated when cytokines or growth factors bind to the receptor, activate JAK, and subsequently recruit STAT. The STAT proteins then translocate to the nucleus and modify gene expression. Altered JAK signaling has been associated with JAK mutations in patients with myelofibrosis.

Immunotherapy

Immunotherapy works by boosting the natural defenses of the host immune system to eradicate tumor cells. These agents work in two main ways: training the individual's immune system to attack cancer directly or by administering immune components that result in a more general stimulation of the immune system. Agents classified as immunotherapies include cytokines, CAR T-cell therapies, immune checkpoint inhibitors, and therapeutic vaccines.

Combination Therapy

Although a single anticancer agent may be administered to a patient, the more common approach to systemic therapy is to administer multiple agents known as a regimen. Initially, this approach was based on the Goldie-Coldman hypothesis, which addresses cancer cell heterogeneity and the inevitable development of drug resistance. The individual agents selected for combination therapy should have different mechanisms of action and adverse drug reaction profiles. For example, myelosuppressive agents may be combined with non-myelosuppressive agents to minimize myelosuppression. The individual agents should each have significant activity against the cancer, and the combination therapy should have known clinical benefit in the cancer to be treated. Combination regimens that include multiple chemotherapy agents with or without a targeted agent or immunotherapy have been used to successfully manage many cancers for decades. Predictive biomarkers, such as HER2 and BRAF, may be used to identify which patients may benefit from targeted therapy.

CHEMOTHERAPY

⑤ Since all chemotherapy agents interfere with the cellular synthesis of DNA, ribonucleic acid (RNA), or proteins, chemotherapy agents are commonly categorized by their mechanism of action. For example, alkylators exert their effects on DNA and protein synthesis by binding to DNA and preventing the unwinding of the DNA molecule. As another example, antimetabolites resemble nucleotide bases or inhibit enzymes involved in synthesizing DNA and proteins. Figure 149-7 shows the sites of action of common categories of anticancer agents.

6-MERCAPTOPURINE
6-THIOGUANINE
Inhibit purine ring biosynthesis
Inhibit DNA synthesis
PEMETREXED
METHOTREXATE
Inhibit dihydrofolate reduction, block thymidylate and purine synthesis
CAMPTOTHECINS
ETOPOSIDE
TENIPOSIDE
DAUNORUBICIN
DOXORUBICIN
Block topoisomerase function
PROTEIN TYROSINE KINASE INHIBITORS, ANTIBODIES
Block activities of signaling pathways
Purine synthesis
Pyrimidine synthesis
Ribonucleotides
Deoxyribo-nucleotides
DNA
RNA
(transfer, messenger, ribosomal)
Proteins
Enzymes
Micro-tubules
Differentiation
HYDROXYUREA
Inhibits ribonucleotide reductase
5-FLUOROURACIL
Inhibits thymidylate synthesis
GEMCITABINE
CYTARABINE
FLUDARABINE
2-CHLORODEOXYADENOSINE
CLOFARABINE
Inhibits DNA synthesis
PLATINUM ANALOGS
ALKYLATING AGENTS
MITOMYCIN
TEMOZOLOMIDE
Form adducts with DNA
L-ASPARAGINASE
Deaminates asparagine
Inhibits protein synthesis
EPOTHILONES
TAXANES
VINCA ALKALOIDS
ESTRAMUSTINE
Inhibit function of microtubules
ATRA
ARSENIC TRIOXIDE
HISTONE DEACELYASE INHIBITORS
Inducers of differentiation

The following sections discuss the biochemical classification system and the individual agents within each classification. The clinical uses, mechanisms of action, common adverse drug reactions, and practical patient management for most available chemotherapy agents are also discussed. Table 149-7 summarizes monitoring parameters of individual anticancer agents.

TABLE 149-7

Monitoring of Anticancer Drugs[a]

Agent	Notable adverse drug reactions	Monitoring Parameters	Comments
Chemotherapeutic Agents			
Antimetabolites			
Capecitabine	Diarrhea, PPE, mild nausea and vomiting, mucositis	Stool count, hands and feet for early signs of skin breakdown, CBC, liver function, renal function	Adjust dose for renal impairment Oral prodrug of fluorouracil Warfarin results in increased anticoagulant effects May require phenytoin dose reduction Deficiency of DPD correlates with increased toxicity
Cladribine	Myelosuppression, fever, immunosuppression, severe opportunistic infections occur	CBC, signs of infection	Risk of opportunistic infections necessitate prophylactic antibiotics for PJP and other infections
Cytarabine	*General toxicities:* myelosuppression, nausea and vomiting, diarrhea, mucositis, TLS, flu-like syndrome, rash *High-dose toxicities:* worsening of above, cerebellar toxicity, conjunctivitis	CBC, uric acid, signs of infection, renal function, neurologic examinations (signs of confusion)	High-dose infusions should be administered over 2-3 hours to decrease risk of CNS toxicity Use corticosteroid eye drops during treatment and for 48 hours after treatment to prevent conjunctivitis with high-dose cytarabine Increased risk of neurotoxicity with high-dose cytarabine in setting of renal impairment Use preservative-free preparations for IT

			preparations: occasionally combined with hydrocortisone & methotrexate
Fludarabine	Myelosuppression, immunosuppression, diarrhea, rare CNS toxicity (somnolence, seizures, altered mental status), hearing and visual changes, pulmonary toxicity, TLS	CBC, uric acid, signs of infection, renal function, neurologic examinations	Adjust dose for renal impairment Risk of opportunistic infections necessitate prophylactic antibiotics for PJP and HSV
Fluorouracil	Mucositis, diarrhea, PPE, myelosuppression, hyperpigmentation, photosensitivity, ocular toxicity, myocardial ischemic symptoms	CBC, stool count, hands and feet for early signs of skin breakdown	Deficiency of DPD correlates with increased toxicity Drug interaction with warfarin: increased anticoagulant effect
Gemcitabine	Myelosuppression, flu-like syndrome, rash, elevations in liver transaminases	CBC, liver function	Fixed dose rate (10mg/m^2/minute) may be used in lymphoma and sarcoma settings, associated with increased myelosuppression
Mercaptopurine	Myelosuppression, dry skin, rash, hepatotoxicity, hyperbilirubinemia	CBC, liver function	Allopurinol increases the toxicity of mercaptopurine by interfering with metabolism Mercaptopurine reduces anticoagulant effects of warfarin Consider pharmacogenomic testing for TPMT and NUDT15
Methotrexate	Myelosuppression, mucositis, renal failure at high doses, nausea and vomiting, CNS toxicity (more severe with IT administration), hepatotoxicity	CBC, liver function, renal function, urine pH, methotrexate drug levels with high-dose therapy	Adjust dose or avoid use with renal impairment, avoid drugs that decrease renal excretion of methotrexate (eg, NSAIDs, PPIs, sulfas, penicillins) Distributes readily into third-space fluids (ascites, pleural effusions), prolonging exposure and increasing toxicity; may be contraindication for use Monitor methotrexate levels with high-dose administration; these must include leucovorin rescue to prevent excessive myelosuppression; sodium bicarbonate given for high-dose therapy to prevent nephrotoxicity (maintain urine pH > 7) Use preservative-free preparations for IT and high-dose administration; occasionally combined with hydrocortisone & cytarabine IT
Pemetrexed	Myelosuppression, stomatitis, pharyngitis, rash, desquamation, fatigue	CBC, renal function, skin examinations	Avoid with renal impairment Avoid NSAIDs during administration Supplement with folic acid (400 - 1000 mcg PO daily starting 1 week before first dose, continued 21 days

			after last dose) and vitamin B_{12} (1,000 mcg IM 7 days prior to first dose and every 3 cycles thereafter) to decrease myelosuppression Premedicate with dexamethasone (day before, the day of, and day after) to decrease incidence of rash
Pentostatin	Myelosuppression, rash, renal toxicity, hepatic toxicity, pulmonary toxicity, CNS toxicity	CBC, renal function, hepatic function, lung function, sign of neurotoxicity	Hydration pre/post pentostatin administration Risk of opportunistic infections necessitate prophylactic antibiotics for PJP and HSV
Trifluridine and tipiracil	Myelosuppression, asthenia/fatigue, decreased appetite, diarrhea, nausea and vomiting, abdominal pain, pyrexia	CBC, renal function	Adjust dose for moderate renal impairment
Microtubule-Targeting Drugs			
Cabazitaxel	Myelosuppression, hypersensitivity reactions, diarrhea, asthenia, nausea and vomiting, peripheral neuropathy, alopecia	CBC, signs of infection, stool count, signs of hypersensitivity reactions, liver function	Avoid with hepatic impairment Premedicate with H_1 and H_2 antagonist plus dexamethasone to decrease risk of hypersensitivity
Docetaxel	Myelosuppression, fluid retention (edema, pleural effusions, ascites) alopecia, rash, peripheral neuropathy, hypersensitivity reactions, nail toxicity	CBC, liver function, signs/symptoms of fluid retention	Contraindicated with hepatic impairment (hyperbilirubinemia, elevated transaminases, or elevated alkaline phosphatase) Premedicate with dexamethasone to lower risk of fluid retention
Eribulin	Myelosuppression, peripheral neuropathy, asthenia, alopecia, nausea, constipation	CBC, liver function, renal function, potassium and magnesium levels	Dose reduce for Child-Pugh class A or B hepatic impairment and moderate renal impairment May cause QTc prolongation in patients with electrolyte or congenital abnormalities (avoid other drugs that may prolong QTc interval)
Ixabepilone	Myelosuppression, peripheral neuropathy, hypersensitivity reactions, asthenia, arthralgias, alopecia	CBC, signs of hypersensitivity reactions, liver function	Avoid or adjust dose with hepatic impairment CYP3A4 substrate, levels may be effected by inducers or inhibitors, avoid use or dose adjustment to ixabepilone may be necessary Premedicate with H_1 and H_2 antagonist
Paclitaxel and nab-paclitaxel	Myelosuppression, hypersensitivity reactions, peripheral neuropathy, myalgias or arthralgias, mucositis, cardiac arrhythmias, alopecia	CBC, signs of hypersensitivity reactions, liver function	Avoid or adjust dose with hepatic impairment Premedicate with dexamethasone, H1 and H2 antagonist before paclitaxel; nab-paclitaxel is associated with minimal risk of hypersensitivity reactions and does not require premedication

			Neurotoxicity may require discontinuation or dose reduction Products are not interchangeable
Vinblastine and vinorelbine	Myelosuppression, mucositis, neurotoxicity (less common than with vincristine), myalgias, SIADH (rarely), vesicant	CBC, liver function	Adjust dose with elevated bilirubin Treat extravasation injury with warm soaks and injection of hyaluronidase
Vincristine	Peripheral neuropathy (highest of vinca alkaloids); motor, sensory, autonomic, and cranial nerves may be affected (paresthesias, ileus, urinary retention, facial palsies) and can be irreversible; SIADH; vesicant	Signs of neurotoxicity (tingling in extremities, constipation, CNS toxicity), liver function	Adjust dose with elevated bilirubin Treat constipation aggressively to prevent ileus Doses are commonly capped at 2 mg to minimize neurotoxicity LETHAL if administered IT Treat extravasation similar to vinblastine
Topoisomerase Inhibitors			
Irinotecan and liposomal irinotecan	Diarrhea: acute (during or immediately after infusion, related to cholinergic effects) and delayed (>24 hours after administration) Nausea and vomiting, myelosuppression, alopecia, fatigue, increased liver enzymes, pulmonary toxicity	CBC, liver function, stool count, fluid status, electrolytes	Acute diarrhea is treated or prevented with atropine, delayed diarrhea is managed with antimotility agents Consider dose adjustment with elevated total bilirubin or UGT1A1 deficiency Products are not interchangeable and have different indications
Topotecan	Myelosuppression, alopecia, diarrhea	CBC, renal function	Adjust dose for renal impairment
Daunorubicin	Myelosuppression, mucositis, nausea and vomiting, alopecia, vesicant Cardiac toxicities: acute (not related to cumulative dose, arrhythmias, pericarditis); chronic (cumulative injury to myocardium with total dose >250 mg/m^2)	CBC, LVEF, liver function	Adjust dose for elevated bilirubin LVEF should be > 50% to administer safely Extravasation managed with dexrazoxane
Doxorubicin and liposomal doxorubicin	Similar to daunorubicin, cardiac toxicity associated with cumulative doses > 250 mg/m^2, radiation recall reactions	CBC, LVEF, liver function	Adjust dose for elevated bilirubin LVEF should be > 50% to administer safely May discolor urine (red-orange) Liposomal form: decreased risk of cardiac and vesicant toxicities
Epirubicin	Similar to daunorubicin, cardiac toxicity associated with cumulative doses > 450 mg/m^2	CBC, LVEF, liver function	Adjust dose for elevated bilirubin LVEF should be > 50% to administer safely

Etoposide	Myelosuppression, nausea and vomiting (may be worse with oral and high-dose regimens), alopecia, mucositis, hypotension (infusion rate–related), hypersensitivity reactions	CBC, blood pressure	Adjust dose for renal impairment Requires large volumes of fluid for IV administration because of limited solubility (maximum concentration 0.4 mg/mL) Available orally in liquid-filled gelatin capsules; ~50% bioavailability but absorption is variable and greater at lower oral doses
Idarubicin	Similar to daunorubicin, total cumulative dose not well established; > 150 mg/m^2 reported to be associated with decreased LVEF	CBC, LVEF, liver function	Adjust dose for elevated bilirubin LVEF should be > 50% to administer safely
Mitoxantrone	Myelosuppression, nausea and vomiting, mucositis, alopecia, less cardiotoxic than the anthracyclines	CBC, LVEF, liver function	Not a vesicant (may cause vein irritation but not associated with severe tissue injury such as anthracyclines) May discolor urine blue-green
Alkylating Agents			
Bendamustine	Myelosuppression, infection, dermatologic reactions including Stevens-Johnson syndrome, TLS, infusion reactions	CBC, signs of infection, signs of dermatologic toxicity, uric acid	Allopurinol may increase risk for Stevens-Johnson syndrome
Busulfan	General toxicities: myelosuppression, skin hyperpigmentation, pulmonary fibrosis, gynecomastia, adrenal insufficiency High (HSCT) dose toxicities: seizures, hepatic veno-occlusive disease, severe nausea and vomiting	CBC, pulmonary status, liver function, signs of edema (weight gain, fluid status)	Bone marrow recovery may be delayed (3-6 weeks), pulmonary fibrosis associated with > 3-year exposure and/or prior chest radiation Seizure prophylaxis with HSCT doses Pharmacokinetic monitoring is required with IV busulfan IV and oral preparations are not interchangeable Put tablets in gelatin capsules for easier administration with high doses
Carboplatin	Myelosuppression (thrombocytopenia), nausea and vomiting (acute and delayed), risk of hypersensitivity reactions at higher cumulative doses (frequently results in cross-hypersensitivity to cisplatin)	CBC, renal function	Calvert formula used to dose carboplatin Lower incidence of nephrotoxicity, neurotoxicity, nausea and vomiting than cisplatin
Chlorambucil	Myelosuppression, increased liver enzymes, skin rash, menstrual irregularities, pulmonary toxicity, risk	CBC, liver function, pulmonary function	Administer on an empty stomach, food decreases absorption May be dosed in low daily-dosing regimens, higher

	of secondary malignancies, infertility and sterility, teratogenic		dose (ie, pulse), or intermittent dosing schedules administered biweekly or monthly; pulse dosing may require patients to take several tablets (eg, 10-20 tablets) per dose
Cisplatin	Nephrotoxicity, potassium and magnesium wasting, severe nausea and vomiting (acute or delayed onset), peripheral neuropathy that is cumulative and dose related, ototoxicity, anemia seen with chronic dosing	Renal function, potassium and magnesium levels, GI symptoms (nausea and vomiting)	Avoid with renal impairment IV hydration required before and after administration; ensure good urine output; potassium and magnesium sulfate in IV fluid to replace losses; consider carboplatin with impaired renal function Aggressive antiemetics required pretreatment and after treatment after to prevent delayed nausea and vomiting Doses should not exceed 100 mg/m^2 (maximum single dose and per-cycle dose)
Cyclophosphamide	Hemorrhagic cystitis, nausea and vomiting (acute and delayed), myelosuppression, alopecia, SIADH (typically with high doses of > 2 g/m^2), risk of secondary malignancies, infertility and sterility	CBC, renal function, urinalysis	Adjust dose for renal impairment Hydration needed to prevent hemorrhagic cystitis (PO or IV); mesna may be required with high-dose regimens (see ifosfamide) Instruct patients to take oral tablets in the morning to allow for elimination of toxic metabolite Absorbed through skin: avoid spills Drug interactions: CYP450 inducers (eg, barbiturates) may increase formation of toxic metabolites; CYP450 inhibitors may increase myelosuppression
Ifosfamide	Hemorrhagic cystitis, nephrotoxicity, myelosuppression, CNS effects (somnolence, confusion, disorientation, cerebellar symptoms that are dose-related), nausea and vomiting (acute and delayed), alopecia	CBC, urinalysis, renal function	Adjust dose for renal impairment 3-4 L/day fluid for hydration; potassium, magnesium, and phosphate may be required to replace losses Mesna is always given (typically 60%-100% of ifosfamide dose); may be delivered in same IV bag CNS toxicity, nausea, and vomiting may be more severe with rapid infusion Methylene blue is controversial for CNS toxicity
Lurbinectedin	Myelosuppression, nausea and vomiting, hepatotoxicity	CBC, liver function, magnesium	Avoid co-administration with strong or moderate CYP3A inducers or inhibitors
Mechlorethamine	Myelosuppression, severe nausea and vomiting, vesicant, secondary malignancies, sterility and infertility	CBC, GI symptoms (nausea and vomiting)	Antidote for extravasation is sodium thiosulfate
Melphalan	Myelosuppression, nausea and vomiting, diarrhea, mucositis, secondary malignancies,	CBC, renal function, electrolytes, liver function	Complete administration of IV dose should occur within 60 min of reconstitution for Alkeran formulation

	hypersensitivity reactions		Melphalan is NOT interchangeable with melphalan flufenamide
Melphalan flufenamide	Myelosuppression, nausea and vomiting, secondary malignancies	CBC, uric acid, ECG	Prophylactic antiviral for HSV and PJP Melphalan flufenamide is NOT interchangeable with melphalan
Nitrosoureas (carmustine and lomustine)	Myelosuppression, severe nausea and vomiting, cumulative nephrotoxicity, pulmonary fibrosis, facial flushing during infusion	CBC, renal function, pulmonary function	Bone marrow recovery may require 6-8 weeks Carmustine is a vein irritant Facial flushing may be related to alcohol vehicle Also available in wafer form for implantation into brain tumor cavities after resection Lomustine is administered orally
Oxaliplatin	Pharyngolaryngeal dysesthesias, nausea and vomiting, anaphylaxis risk Peripheral neuropathy > 50% patients: acute form (< 14 days, rapid onset, reversible, exacerbated by cold); chronic form (onset > 14 days and may be permanent)	CBC, renal function, acute and chronic neuropathies	Adjust dose for renal impairment Avoid exposure to cold
Procarbazine	Myelosuppression, diarrhea, neurotoxicity, neuropathy, flu-like syndrome, infertility and sterility, secondary malignancies	CBC	Administer as a single daily dose on an empty stomach Drug interactions: MAOIs that interact with tyramine-rich foods and may precipitate hypertensive crisis; TCAs and SSRIs; sympathomimetics; disulfiram-like reaction with alcohol
Thiotepa	Myelosuppression, nausea and vomiting, mucositis, pruritus and dermatitis	CBC, dermatologic toxicities	Most commonly used in HSCT preparative regimens
Trabectedin	Myelosuppression, rhabdomyolysis, hepatotoxicity, nausea and vomiting, diarrhea or constipation, cardiomyopathy	CBC, CPK, liver function	Extravasation may lead to tissue necrosis
Triazenes (dacarbazine and temozolomide)	Myelosuppression, severe nausea and vomiting, increased liver enzymes, flu-like syndrome (may last for several days after dacarbazine administration), facial flushing, photosensitivity	CBC, liver function	Dispense in a light-proof bags Temozolomide crosses the blood-brain barrier, may cause lymphosuppression and requires PJP prophylaxis when given with radiation therapy
DNA Methyltransferase Inhibitors			

Azacitidine and decitabine	Myelosuppression and infection, constitutional symptoms, musculoskeletal symptoms (arthralgias), cough, dyspnea	CBC, infection	Oral formulation decitabine/cedazuridine available
Immunomodulatory Imide Drugs			
Lenalidomide	Teratogen, fatigue, peripheral neuropathy, neutropenia and thrombocytopenia, thromboembolic events	CBC, signs of thrombosis, signs of peripheral neuropathies, pregnancy status	REMS program for fetal toxicity Adjust dose for renal impairment Prophylactic anticoagulation may be required
Pomalidomide	Teratogen, neutropenia, hepatotoxicity, thromboembolic events	Same as for lenalidomide	REMS program for fetal toxicity Adjust dose for renal and hepatic impairment Prophylactic anticoagulation may be required
Thalidomide	Teratogen, somnolence, constipation, dizziness or orthostatic hypotension, rash, peripheral neuropathy, thromboembolic events, increased HIV viral load	Same as for lenalidomide	REMS program for fetal toxicity Prophylactic anticoagulation may be required
Retinoids			
Bexarotene	Peripheral edema, insomnia, headache, fever, increased triglycerides and cholesterol, hypothyroidism, leukopenia and anemia, dry skin, increased liver enzymes, pancreatitis, photosensitivity	CBC, liver function, cholesterol and triglyceride levels, thyroid function	Avoid gemfibrozil to treat elevated triglycerides Limit vitamin A supplements May cause hypoglycemia in patients receiving insulin, sulfonylureas, or metformin Teratogenic, contraindicated in pregnancy, patients should be educated about proper contraceptive measures
Tretinoin	Headache, differentiation syndrome (consisting of pulmonary symptoms, fever, hypotension, and pleural effusions), dry skin and mucous membranes, mucositis, increases in liver enzymes and bilirubin	CBC, liver function, signs of differentiation syndrome	Differentiation syndrome must be treated promptly with corticosteroids Teratogenic, contraindicated in pregnancy, patients should be educated about proper contraceptive measures
Miscellaneous Agents			
Arsenic trioxide	Differentiation syndrome (pulmonary infiltrates, respiratory distress, fever, and hypotension), QTc prolongation, electrolyte abnormalities	ECG, serum electrolytes (calcium, magnesium, potassium), renal	Differentiation syndrome must be treated promptly with corticosteroids Do not give if QTc > 500 msec Replace electrolytes before therapy

	(hypokalemia, hyperkalemia, hypomagnesemia), hyperglycemia, rash, lightheadedness, fatigue, musculoskeletal pain	function	
Asparaginase	Anaphylaxis, thrombosis, pancreatitis, glucose intolerance, hemorrhage, hepatotoxicity	Pancreatic enzymes, liver function, glucose, coagulation parameters (fibrinogen, PT, PTT), hypersensitivity reactions, blood glucose, CBC	FDA-approved products include L-asparaginase, recombinant asparaginase (*Erwinia*), pegaspargase, and calaspargase pegol
Bleomycin	Anaphylaxis and hypersensitivity reactions, fever and flu-like symptoms, mucositis, pulmonary fibrosis	Obtain PFTs before use and if signs of pulmonary toxicity develop, monitor for anaphylactic reactions	Adjust dose for renal impairment Test dose (1 unit) is recommended but controversial; premedicate for subsequent doses with acetaminophen Pulmonary toxicity associated with cumulative dose > 400 units and pre-existing pulmonary disease
Hydroxyurea	Myelosuppression, rash, skin hyperpigmentation, TLS, secondary leukemias	CBC, uric acid	Dose may need to be adjusted with renal impairment (use with caution) Used to decrease white blood cell counts rapidly to prevent adverse effects of leukocytosis
Lanreotide	Abdominal pain, musculoskeletal pain, vomiting, headache, injection site reaction, hypertension, glucose abnormalities	Glucose, thyroid function, heart rate	Cholelithiasis and complications of cholelithiasis May need to adjust anti-diabetic medications in diabetic patients May decrease heart rate, use with caution in at-risk patients
Mitomycin	Myelosuppression (delayed and prolonged), mucositis, nausea and vomiting, vesicant, pulmonary fibrosis, hemolytic anemia and uremic syndrome	CBC, renal function, pulmonary function	Apply ice or cold packs to site for extravasation May be given intravenously or by intravesical administration; also available as a ureteral gel formulation
Omacetaxine	Myelosuppression (thrombocytopenia including increased risk of hemorrhage, anemia, neutropenia), diarrhea, nausea, fatigue, asthenia, injection site reaction, pyrexia, infection, lymphopenia, hyperglycemia	CBC, blood glucose	
Targeted Agents: Small Molecules			

Anaplastic Lymphoma Kinase (ALK) Inhibitors			
Alectinib	Fatigue, bradycardia, hepatotoxicity, anemia, constipation, edema, myalgia, visual disturbances	CBC, liver function, heart rate, CPK	Administer with food
Brigatinib	ILD and pneumonitis, hypertension, bradycardia, visual disturbances, CPK elevation, pancreatic enzyme elevation, hyperglycemia	HR, BP, pulmonary symptoms, CPK, pancreatic enzymes	Dose escalation required to decrease early-onset pulmonary symptoms Avoid strong CYP3A inhibitors and inducers; may affect hormonal contraceptives
Ceritinib	Gastrointestinal toxicity, increases in liver enzymes, fatigue, visual disturbances, QTc prolongation, bradycardia, hyperglycemia	CBC, renal function, liver function, blood glucose, pancreatic enzymes, cardiac monitoring, electrolytes	Administer on an empty stomach
Crizotinib	Nausea and vomiting, diarrhea, constipation, fatigue, increases in liver enzymes, visual disorders, edema, ILD, QTc prolongation, bradycardia	CBC, renal function, liver function, HR, BP, cardiac monitoring, electrolytes, pulmonary symptoms	Visual disorders (visual impairment, blurred vision, and photopsia) occur in approximately 50% of patients
Lorlatinib	Hepatotoxicity, CNS toxicity, hyperlipidemia, atrioventricular block, ILD and pneumonitis	Liver function, lipids, ECG	Strong CYP3A inducers are contraindicated, avoid strong CYP3A4 inhibitors and CYP3A4 substrates
B-Cell Lymphoma 2 (BCL-2) Inhibitors			
Venetoclax	TLS, myelosuppression, diarrhea, upper respiratory tract infection	CBC, uric acid, electrolytes	Ramp-up dose required Premedicate with anti-hyperuricemics and ensure adequate hydration Contraindicated with strong CYP3A inhibitors during initiation and ramp-up Avoid strong and moderate CYP3A inhibitors, strong or moderate CYP3A inducers, P-gp inhibitors, or narrow therapeutic substrates Avoid live-attenuated vaccines Administer with a meal
Breakpoint Cluster Region-Abelson (BCR-ABL) Inhibitors			
Bosutinib	Nausea and vomiting, edema, pleural effusions and ascites, myelosuppression, CHF, arthralgias,	CBC, liver function, electrolytes, Philadelphia	Adjust dose for hepatic impairment Avoid antacids and PPIs Maintenance dose based on CBC

	rash, diarrhea, increased liver enzymes, hypophosphatemia	chromosome levels, signs of edema	Administer with food
Dasatinib	Nausea and vomiting, edema, pleural effusions and ascites, myelosuppression, CHF, arthralgias, fatigue, rash, diarrhea, increased liver enzymes, QTc prolongation, hypophosphatemia, hypocalcemia	CBC, liver function, electrolytes, signs of edema, Philadelphia chromosome levels	Avoid antacids, H_2 antagonists, and PPIs Maintenance dose based on CBC
Imatinib	Nausea and vomiting, edema, pleural effusions and ascites, myelosuppression, CHF, arthralgias, rash, diarrhea, increased liver enzymes, hypophosphatemia	CBC, liver function, electrolytes, Philadelphia chromosome levels, signs of edema	Dose adjustments should be considered with severe liver and moderate renal impairment May increase warfarin effects Maintenance dose based on CBC Take with meals and a full glass of water
Nilotinib	Nausea and vomiting, edema, myelosuppression, increased lipase, hyperglycemia, arthralgias, rash, diarrhea, increased liver enzymes, QTc prolongation	CBC, liver function, serum lipase, serum glucose, electrolytes, Philadelphia chromosome levels	Adjust dose for hepatic impairment Take on an empty stomach CYP3A4 substrate: avoid inhibitors Maintenance dose based on CBC Avoid PPIs, stagger administration with H_2 antagonists and antacids if use is necessary
Ponatinib	Myelosuppression, hypertension, rash, abdominal pain, fatigue, headache, dry skin, constipation, arthralgia, nausea, pyrexia, thromboembolic events, hepatotoxicity, CHF, pancreatitis, hemorrhage (secondary to thrombocytopenia), fluid retention	Cardiac monitoring (CHF, arrhythmias), BP, pancreatic enzymes, fluid retention, CBC, liver function	May need to decrease dose or hold therapy if hepatotoxicity develops Avoid antacids and drugs that decrease gastric pH
BRAF Inhibitors			
Dabrafenib	Papilloma, arthralgia, alopecia, fatigue, headache, PPE, pyrexia	CBC, serum glucose, electrolytes, renal function, dermatologic evaluations	Take on an empty stomach
Encorafenib	Cutaneous and non-cutaneous malignancies, hemorrhage, uveitis, QTc prolongation	Visual symptoms, ophthalmologic evaluations, ECG, electrolytes	Avoid strong and moderate CYP3A inhibitors, strong inducers, and sensitive CYP3A substrates Use nonhormonal contraceptives
Vemurafenib	Papilloma, arthralgia, alopecia, fatigue, headache, photosensitivity reaction, hypersensitivity reactions, QTc	Liver function, electrolytes, cardiac monitoring,	Radiation sensitization/recall

	prolongation	dermatologic evaluations	
Bruton's Tyrosine Kinase (BTK) Inhibitors			
Acalabrutinib	Infections, secondary primary malignancies, atrial flutter and fibrillation	CBC, cardiac monitoring	Avoid strong CYP3A inhibitors, strong CYP3A inducers Avoid PPIs, stagger administration with H_2 antagonists and antacids if use is necessary
Ibrutinib	Diarrhea, fatigue, musculoskeletal pain, nausea, rash, atrial fibrillation, hemorrhage, TLS, myelosuppression	CBC, renal function, liver function, uric acid levels, electrolytes, cardiac monitoring	Reduce dose with hepatic impairment Dose modifications for use with CYP3A inhibitors or inducers
Zanubrutinib	Myelosuppression, infections, secondary malignancies, cardiac arrhythmias, hemorrhage, rash, bruising, diarrhea, cough	CBC, liver function	Dose modifications for use with CYP3A inhibitors or inducers
Cyclin-Dependent Kinase (CDK) Inhibitors			
Abemaciclib	Diarrhea, neutropenia, hepatotoxicity, venous thromboembolism	CBC, electrolytes, liver function	Avoid moderate and strong CY3A inducers Dose reduce with moderate and strong CYP3A inhibitors Reduce dose with severe hepatic impairment
Palbociclib	Thromboembolic events, infection, bone marrow suppression, gastrointestinal toxicity	CBC, infection	Administer with food
Ribociclib	QTc prolongation, hepatobiliary toxicity, neutropenia	ECG, electrolytes, liver function, CBC	Avoid drugs known to prolong QTc interval, strong CYP3A inhibitors, strong CYP3A inducers, sensitive CYP3A substrates
Colony-Stimulating Factor-1 Receptor (CSF-1R) Inhibitors			
Pexidartinib	Hepatotoxicity, hair color change, rash, dysgeusia, edema of eyelid, fatigue	Liver function, creatinine clearance	REMS program for liver toxicity Dose adjustment for renal and hepatic impairment Take on empty stomach Acid-reducing agents: Administer pexidartinib 2 hours before or 2 hours after locally-acting antacids; administer pexidartinib ≥ 2 hours before or 10 hours after a H2-receptor antagonist; avoid concomitant administration of pexidartinib with PPIs
Epidermal Growth Factor Receptor (EGFR) Inhibitors			

Afatinib	Rash, diarrhea, ILD, keratitis, stomatitis	Liver function, renal function, dermatologic evaluations, electrolytes, LVEF in patients with cardiac risk factors, pulmonary symptoms	Administer on an empty stomach
Dacomitinib	ILD, diarrhea, dermatologic toxicity	Pulmonary symptoms, skin	Avoid PPIs and sensitive CYP2D6 inhibitors Initiate use of moisturizers and appropriate measures to limit sun exposure
Erlotinib	Rash, diarrhea, ILD, hepatic and renal failure reported	Liver function, renal function, electrolytes, pulmonary symptoms, dermatologic evaluations	Dose reductions or delays may be required for rash but supportive care should be attempted first Major interaction with warfarin (may lead to increased bleeding risk) H_2 antagonists, PPIs, and antacids may decrease drug levels Administer on an empty stomach as food increases absorption and possibly toxicity
Gefitinib	Similar to erlotinib	Liver function, renal function, electrolytes, pulmonary symptoms, dermatologic evaluations	Similar precautions and drug interactions as with erlotinib
Osimertinib	Gastrointestinal toxicity, dermatologic toxicity, ILD/pneumonitis, pneumonia, pulmonary embolism, cardiomyopathy, QTc prolongation	Cardiac monitoring (LVEF, QTc), pulmonary symptoms, dermatologic evaluations	Avoid strong CYP3A4 inhibitors and inducers Avoid drugs that prolong QTc
Enhancer of Zeste Homolog 2 (EZH2) Inhibitors			
Tazemetostat	Myelosuppression, fatigue, nausea and vomiting, secondary malignancies	CBC	Avoid moderate/strong CYP3A4 inhibitors or inducers
Fibroblast Growth Factor Receptor (*FGFR) Inhibitors*			
Erdafitinib and Pemigatinib	Ocular disorders, hyperphosphatemia, stomatitis, creatinine increased, PPE,	Ophthalmological exams, phosphate	Avoid moderate/strong CYP2C9 or CYP3A4 inhibitors and inducers

	elevated liver enzymes	levels	Increased phosphate levels are a pharmacodynamic effect
FMS-Like Tyrosine Kinase-3 (FLT3) Inhibitors			
Gilteritinib	PRES, QTc prolongation, pancreatitis, hypersensitivity	ECG, electrolytes	Avoid dual P-gp and CYP3A inducers and strong CYP3A inhibitors
Midostaurin	Pulmonary toxicity	ECG	Administer with food Avoid strong CYP3A inducers
Hedgehog Inhibitors			
Glasdegib	QTc prolongation, teratogenic effects	Pregnancy status, ECG	Boxed warning for severe birth defects and embryo-fetal death; advise females to use contraception during treatment and for 20 months after the last dose; advise males to use condoms during treatment and for at least 8 months after the last dose; do not donate blood during treatment and for 30 months after the last dose; do not donate sperm during treatment and for 8 months after the last dose
Sonidegib	Fatigue, alopecia, amenorrhea, musculoskeletal toxicity, teratogenic effects	Pregnancy status, CPK, renal function, liver function	Boxed warning for severe birth defects and embryo-fetal death; advise females to use contraception during treatment and for 20 months after the last dose; advise males to use condoms during treatment and for at least 8 months after the last dose; do not donate blood during treatment and for 20 months after the last dose; do not donate sperm during treatment and for 8 months after the last dose Avoid strong and moderate CYP3A modulators; moderate CYP3A inhibitors may be used for short term
Vismodegib	Muscle spasms, alopecia, dysgeusia, fatigue, nausea and vomiting, diarrhea, decreased appetite, constipation, arthralgias, teratogenic effects	Pregnancy status	Boxed warning for severe birth defects and embryo-fetal death; patients should not donate blood or blood products while receiving vismodegib and for at least 7 months after the last dose; verify pregnancy status within 7 days prior to treatment initiation; do not donate sperm during treatment and for 3 months after the last dose
Human Epidermal Growth Factor Receptor 2 (HER2) Inhibitors			
Lapatinib	Diarrhea, rash, nausea, vomiting, fatigue, decreases in LVEF, hepatotoxicity, QTc prolongation, ILD	Liver function, cardiac monitoring (LVEF, QTc),	Adjust dose for severe hepatic impairment Administer on empty stomach Avoid strong CYP3A4 inhibitors (if unavoidable,

		electrolytes, pulmonary symptoms	consider dose reduction), avoid strong CYP3A4 inducers (if unavoidable, consider gradual dose increases)
Neratinib	Diarrhea, hepatotoxicity	Liver function, electrolytes	Use prophylactic antidiarrheals Lower starting dose for hepatic impairment Avoid PPIs, strong and moderate CYP3A inhibitors, strong and moderate CYP3A inducers, and sensitive P-gp substrates
Tucatinib	Diarrhea, hepatotoxicity	Liver function, Child-Pugh Score, stool count	Dose adjustment recommended for hepatic impairment
Histone Deacetylase (HDAC) Inhibitors			
Belinostat	Pyrexia, nausea, fatigue, anemia, hepatotoxicity, infection, TLS	Liver function, renal function, CBC, uric acid levels	Empiric dose reduction in patients known to be homozygous for UGT1A1*28 allele
Panobinostat	Cardiotoxicity, nausea and vomiting, diarrhea, hemorrhage, infection, hepatotoxicity	Cardiac monitoring, electrolytes, CBC, liver function, pregnancy status	Boxed warnings for cardiovascular events and gastrointestinal events
Romidepsin	Myelosuppression, infection, nausea and vomiting, fatigue, anorexia, ECG T-wave changes	CBC, cardiac monitoring (ECG), electrolytes	Monitor INR with concurrent use of warfarin
Vorinostat	Diarrhea, fatigue, nausea, thrombocytopenia, anorexia, dysgeusia, thromboembolic events, hyperglycemia	CBC, electrolytes, serum glucose, renal function	Avoid or adjust dose for hepatic impairment Increase in INR with concomitant warfarin Severe thrombocytopenia and GI bleeding have been reported with concomitant use with vorinostat and other HDAC inhibitors (eg, valproic acid)
Isocitrate Dehydrogenase (IDH) Inhibitors			
Enasidenib	Differentiation syndrome, TLS, myelosuppression, hepatotoxicity, nausea and vomiting	CBC, electrolytes, signs of differentiation syndrome	Differentiation syndrome maybe life-threatening. If suspected, initiate oral or intravenous corticosteroids and hemodynamic monitoring until improvement Decrease dosage of OATP1B1, OATP1B3, BCRP, and P-gp substrates with co-administration
Ivosidenib	Differentiation syndrome, QTc prolongation, Guillain-Barré Syndrome, TLS	CBC, chemistries, CPK, ECG, electrolytes, signs of differentiation syndrome	Differentiation syndrome maybe life-threatening. If suspected, initiate oral or intravenous corticosteroids and hemodynamic monitoring until improvement Reduce ivosidenib dose with strong CYP3A4 inhibitors Avoid strong CYP3A inducers; sensitive CYP3A

			substrates; drugs that prolong QTc interval Avoid high-fat meal
Janus Kinase (JAK) Inhibitors			
Fedratinib	Encephalopathy, thrombocytopenia, anemia, nausea and vomiting, diarrhea, hepatotoxicity, amylase/lipase elevations	CBC, liver function, thiamine, symptoms of encephalopathy, pancreatic enzymes	Assess and replete thiamine at baseline and periodically Avoid co-administration with strong and moderate CYP3A4 inducers; avoid dual CYP3A4 and CYP2C19 inhibitors; and reduce fedratinib dose with strong CYP3A4 inhibitors Reduce dose for severe renal impairment, avoid use with severe hepatic impairment
Ruxolitinib	Thrombocytopenia, anemia, bruising, dizziness, headache, infections, cardiovascular abnormalities	CBC, renal function, liver function, cardiac monitoring	Consider dose adjustment for renal and hepatic impairment
Mitogen-Activated Protein Kinase-Extracellular Signal-Regulated Kinase (MEK) Inhibitors			
Binimetinib	Cardiomyopathy, venous thromboembolism, ILD, hepatotoxicity, rhabdomyolysis, hemorrhage, ophthalmic events	LVEF, ophthalmologic evaluation, liver function, CPK, renal function	Reduce dose for moderate and severe hepatic impairment
Cobimetinib and Selumetinib	Dermatologic toxicity, nausea and vomiting, pyrexia, hemorrhage, new primary malignancies, cardiomyopathy, ophthalmic events, hepatotoxicity, rhabdomyolysis	CBC, liver function, dermatologic evaluation, ophthalmologic evaluation, LVEF, CPK, electrolytes	Avoid coadministration with strong or moderate CYP3A inducers or inhibitors Selumetinib capsules contain vitamin E which may result in increased vitamin E levels and risk of bleeding
Trametinib	Diarrhea, lymphedema, hemorrhage, venous thromboembolism, febrile reactions, cardiomyopathy, dermatologic toxicity, hyperglycemia, hypertension, ophthalmic events	CBC, liver function, LVEF, ophthalmologic evaluation, dermatologic evaluation, BP	Capsules are stored refrigerated Administer on an empty stomach
Mesenchymal-Epithelial Transition (MET) Inhibitors			
Tepotinib and Capmatinib	Edema, fatigue, hepatotoxicity, dyspnea, musculoskeletal pain	Liver function, pulmonary symptoms	Modify dose for hepatotoxicity during treatment Take tepotinib with food
Mammalian Target of Rapamycin (mTOR) Inhibitors			
Everolimus	Rash, asthenia, stomatitis, nausea,	Metabolic toxicities,	Adjust dose for hepatic impairment

	edema, anorexia, anemia, pneumonitis, hyperglycemia, hyperlipidemia, hypertriglyceridemia, hypophosphatemia, elevated liver enzymes, elevated creatinine, lymphopenia, thrombocytopenia, leukopenia, infection	CBC, renal function, liver function, electrolytes, pulmonary symptoms	Cholesterol or diabetic medications may need to be initiated or dosages increased CYP3A4 and P-gp substrate; may require dose adjustment based on concurrent medication
Temsirolimus	Similar to everolimus with addition of infusion-related reactions	Similar to everolimus, infusion reactions	Adjust dose for hepatic impairment Requires diphenhydramine premedication
Nuclear Export Inhibitors			
Selinexor	Myelosuppression, nausea and vomiting, hyponatremia, diarrhea, weight loss, loss of appetite, neurotoxicity	CBC, electrolytes, volume status, weight	Dose adjustment for hyponatremia Maintain adequate fluid and caloric intake throughout treatment and consider IV hydration in patients at risk of dehydration
Poly ADP Ribose Polymerase (PARP) Inhibitors			
Niraparib	MDS/AML, myelosuppression, cardiovascular toxicity	CBC, liver function, BP, HR	Dose adjust for hepatic impairment and myelosuppression
Olaparib	MDS/AML, fatigue, musculoskeletal pain, dermatitis, nausea and vomiting, upper respiratory infections, anemia, pneumonitis	CBC, pulmonary symptoms	Reduce dose for renal impairment
Rucaparib	MDS/AML, nausea and vomiting	CBC	Adjust dose of CYP1A2, CYP3A, CYP2C9 or CYP2C19 substrates, if clinically indicated. If co-administration with warfarin cannot be avoided, consider increasing the frequency of INR monitoring.
Talazoparib	MDS/AML, myelosuppression	CBC, renal function	Reduce starting dose for renal impairment Reduce dose with certain P-gp inhibitors
Platelet-Derived Growth Factor Receptor-alpha (PDGFR-α) Inhibitors			
Avapritinib	Edema, hair color change, rash, abdominal pain, fatigue, excessive tear production, anemia, CNS toxicity	Liver function, CBC	Dose adjustment for hepatic impairment Dose adjustment for concomitant CYP3A4 inhibitors Take on empty stomach
Ripretinib	Arthralgia/myalgia, hypertension, LV dysfunction, dermatologic toxicity, alopecia, abdominal pain,	LVEF, BP, dermatologic evaluation	Withhold for at least 1 week prior to elective surgery; do not administer for at least 2 weeks following major surgery and until adequate wound healing

	constipation, diarrhea, nausea and vomiting		
Phosphatidylinositide 3-Kinase (PI3K) Inhibitors			
Alpelisib	Dermatologic reactions, severe diarrhea, pneumonitis, hyperglycemia, severe hypersensitivity reactions	Blood glucose, dermatologic evaluation, pulmonary symptoms	Avoid strong CYP3A inducers, closely monitor with concurrent CYP2C9 substrates (eg, warfarin)
Copanlisib	Infections, hyperglycemia, hypertension, pneumonitis, neutropenia, dermatologic reactions	CBC, blood glucose, BP	Reduce dose with strong CYP3A inhibitors; avoid strong CYP3A inducers Consider PJP prophylaxis
Duvelisib	Infections, neutropenia, fatal/serious diarrhea, dermatologic reactions, pneumonitis, hepatotoxicity	CBC, liver function, dermatologic evaluation, pulmonary symptoms, GI symptoms	REMS program for infections, diarrhea/colitis, cutaneous reactions, and pneumonitis Avoid strong CYP3A inducers; reduce moderate and strong CYP3A inhibitors PJP prophylaxis required; consider antiviral prophylaxis for CMV
Idelalisib	Fatal/serious diarrhea, intestinal perforation, hepatotoxicity, pneumonitis, infections, neutropenia, dermatologic reactions, anaphylaxis	Liver function, CBC, dermatologic evaluation, pulmonary symptoms, GI symptoms	REMS program for hepatoxicity, diarrhea/colitis, pneumonitis, infections, intestinal perforation PJP prophylaxis required
Umbralisib	Increased serum creatinine, infections, dermatologic reactions, decreased potassium, myelosuppression, hepatoxicity, abdominal pain, decreased appetite, diarrhea, nausea and vomiting	CBC, liver function, symptoms of infection, dermatologic evaluations	PJP prophylaxis required Consider prophylactic antivirals to prevent CMV
Proteasome Inhibitors			
Bortezomib	Fatigue or malaise, nausea and vomiting, diarrhea, anorexia, constipation, myelosuppression (especially thrombocytopenia), hyponatremia, hypokalemia, peripheral neuropathy (cumulative and dose-related), fever	CBC, thyroid function, symptoms of neuropathy, electrolytes	Adjust dose for hepatic impairment Administer IV or subcutaneous (subcutaneous administration has been shown to decrease neuropathies); increased risk of severe neuropathy with pre-existing neuropathy Co-administration with strong CYP3A4 inhibitors can increase bortezomib concentrations
Carfilzomib	Fatigue, anemia, thrombocytopenia,	Pulmonary	Premedicate with dexamethasone before all cycle 1

	nausea, diarrhea, dyspnea, pyrexia, infusion-related reactions, rare reports of cardiac arrest, CHF, and MI	symptoms, CBC, liver function, cardiac monitoring, infusion reactions	doses then as needed for future cycles to reduce the incidence of infusion reactions
Ixazomib	Gastrointestinal toxicity, thrombocytopenia, peripheral neuropathy, edema, cutaneous reactions, hepatotoxicity	CBC, liver function, dermatologic evaluation	Administer on an empty stomach Reduce starting dose for hepatic or renal impairment Avoid use with strong CYP3A4 inducers Consider antiviral prophylaxis
Ras Inhibitors			
Sotorasib	Hepatotoxicity, interstitial lung disease, diarrhea, musculoskeletal pain, fatigue, cough	Pulmonary symptoms, liver function	Avoid co-administration with PPIs and H2 antagonists Avoid co-administration with strong CYP3A4 inducers, CYP3A4 substrates, and P-gp substrates
Rearranged during Transfection (RET) Inhibitors			
Pralsetinib	Edema, constipation, diarrhea, hepatoxicity, musculoskeletal pain, cough, fatigue, hypertension	Liver function, BP	Take on empty stomach Avoid use with strong CYP3A4 inducers and inhibitors Withhold at least 5 days prior to elective surgery. Do not administer for at least 2 weeks after surgery and until adequate wound healing
Selpercatinib	Thrombocytopenia, hemorrhage, hypertension, QTc prolongation, rash, constipation, diarrhea, xerostomia, impaired wound healing	CBC, liver function, BP, QTc	Avoid moderate/strong CYP3A inhibitors Avoid PPIs, H2 antagonists, and antacids Dose adjustment with hepatic impairment Withhold for at least 1 week prior to elective surgery; do not administer for at least 2 weeks following major surgery and until adequate wound healing
Tropomyosin Receptor Kinase (TRK) Inhibitors			
Entrectinib	Cardiotoxicity, CNS toxicity, hepatoxicity, vision disorders, skeletal fractures	CBC, liver function, uric acid, ECG, electrolytes	Avoid strong CYP3A inhibitors, if co-administration cannot be avoided, dose adjust entrectinib
Larotrectinib	Neurotoxicity, hepatotoxicity	Liver function	Avoid strong CYP3A inhibitors and inducers; avoid sensitive CYP3A substrates Reduce starting dose in moderate or severe hepatic impairment
Vascular Endothelial Growth Factor Receptor (VEGFR) Multikinase Inhibitors			
Axitinib	Diarrhea, rash, PPE, bleeding, thrombotic events, hypertension, hepatotoxicity, hypothyroidism,	CBC, liver function, BP, thyroid function, urine protein,	Blood pressure should be well-controlled prior to administration Hold for at least 2 days prior to elective surgery and

	proteinuria, GI perforation, fatigue, rare reports of RPLS	neurologic evaluation, dermatologic evaluation	do not administer for at least 2 weeks following major surgery and until adequate wound healing Adjust dose for hepatic impairment Substrate of CYP3A4, may require dose adjustment based on concurrently administered medication
Cabozantinib	Diarrhea, stomatitis, PPE, decreased weight, decreased appetite, nausea, fatigue, oral pain, hair color changes, dysgeusia, hypertension, abdominal pain, constipation, increased liver enzymes, proteinuria, lymphopenia, neutropenia, thrombocytopenia, hypocalcemia, hypophosphatemia, GI perforations and fistulas, hemorrhage	BP, urine protein, CBC, liver function, thyroid function, electrolytes, dermatologic evaluation	Blood pressure should be well-controlled prior to administration Hold for at least 3 weeks prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Adjust dose for hepatic impairment Substrate of CYP3A4, may require dose adjustment based on concurrently administered medication
Lenvatinib	Hypertension, fatigue, diarrhea, proteinuria, stomatitis, PPE, hypothyroidism, hepatotoxicity, thromboembolic events, renal toxicity, hypocalcemia, GI perforation	Liver function, renal function, thyroid function, BP, electrolytes	Blood pressure should be well-controlled prior to administration Hold for at least 1 week prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Adjust dose for severe hepatic and renal impairment Weight-based dosing for HCC
Pazopanib	Diarrhea, hypertension, hair/skin hypopigmentation, nausea, anorexia, vomiting, decreased weight, fatigue, musculoskeletal pain, dysgeusia, dyspnea, hypothyroidism, proteinuria, fatal hepatotoxicity, thromboembolic events	Liver function, cardiac monitoring (ECG), BP, thyroid function, urine protein, dermatologic evaluation	Blood pressure should be well-controlled prior to administration Hold for at least 1 week prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Adjust dose for hepatic impairment Take on empty stomach Reduce dose when administered with strong CYP3A4 inhibitors, avoid CYP3A4 inducers, concomitant use with simvastatin increases liver enzymes
Regorafenib	Asthenia, fatigue, decreased appetite, PPE, diarrhea, mucositis, weight loss, infection, hypertension, dysphonia, hepatotoxicity, hemorrhage	Liver function, BP, dermatologic evaluation	Blood pressure should be well-controlled prior to administration Hold for at least 2 weeks prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Administer with food (low-fat breakfast that contains < 30% fat) Monitor INR closely with concomitant warfarin because of an increased risk of hemorrhage
Sorafenib	Diarrhea, rash, PPE, fatigue, hypertension, prolonged QTc interval,	BP, liver function, cardiac monitoring,	Blood pressure should be well-controlled prior to administration

	cardiac events (including MI), hepatitis	electrolytes, dermatologic evaluation	Hold for at least 10 days prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Administer on an empty stomach May increase the anticoagulation effects of warfarin
Sunitinib	Diarrhea, rash, bleeding, CHF and cardiac effects, QTc prolongation, fatigue, hypertension, hepatotoxicity, thyroid dysfunction	CBC, liver function, BP, thyroid function, cardiac monitoring (CHF, ECG), electrolytes	Blood pressure should be well-controlled prior to administration Hold for at least 3 weeks prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing CYP3A4 substrate, may require dose adjustment based on concurrent medications
Tivozanib	Diarrhea, hypertension, decrease appetite, stomatitis, thyroid dysfunction, proteinuria, thromboembolic events	BP, liver function, proteinuria, thyroid function	Blood pressure should be well-controlled prior to administration Hold for at least 24 days prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing Avoid strong CYP3A4 inducers Dose adjustment for hepatic impairment
Vandetanib	Diarrhea, rash, acne, nausea, hypertension, headache, fatigue, upper respiratory tract infections, decreased appetite, abdominal pain, QTc prolongation, torsades de pointes and sudden death, ILD, hemorrhage, increased liver enzymes	Liver function, electrolytes, cardiac monitoring (ECG), BP, pulmonary symptoms, dermatologic evaluation	Hold for at least 1 month prior to elective surgery and do not administer for at least 2 weeks following major surgery and until adequate wound healing REMS program for QTc prolongation and sudden death; avoid other medications that prolong the QTc interval Adjust dose for renal impairment Advise patients to wear sunscreen and protective clothing when exposed to sun
Targeted Agents: mAbs & ADCs			
Antibodies that Target BCMA (B-Cell Maturation Antigen)			
Belantamab mafodotin	Myelosuppression, ocular toxicity, infusion-related reactions, electrolyte abnormalities, transaminitis	CBC, complete metabolic panel, infusion-related reactions, ophthalmic evaluations	ADC with payload MMAF (a microtubule disrupting agent) REMS program because of risk of ocular toxicity Patients should use preservative-free lubricant eye drops at least 4 times a day, starting with the initial infusion and continuing until the end of therapy; avoid contact lenses unless otherwise directed
Antibodies that Target CD19			
Loncastuximab	Myelosuppression, edema,	CBC, infection, skin	ADC with payload SG3199 (an alkylating agent)

tesirine	dermatologic toxicity, musculoskeletal pain	evaluation	Premedicate with dexamethasone
Tafasitamab	Myelosuppression, infusion-related reactions, edema, decrease appetite, diarrhea, fatigue, fever	CBC, infusion-related reactions, infection	Premedication (may include acetaminophen, an H1 receptor antagonist, an H2 receptor antagonist, and/or glucocorticoids) for initial infusion, may discontinue for subsequent infusions
Antibodies that Target CD20			
Obinutuzumab	Infusion-related reactions, myelosuppression, nausea, diarrhea, PML, HBV reactivation	CBC, hepatitis B screening at baseline, renal function, electrolytes, infusion-related reactions, fluid status	Patients should be screened for hepatitis B before therapy initiation Antimicrobial, antiviral, and antifungal prophylaxis in select patients Anti-hyperuricemic prophylaxis and hydration if risk for TLS Premedicate with acetaminophen, an antihistamine, and a glucocorticoid
Ofatumumab	Neutropenia, pneumonia, pyrexia, cough, diarrhea, anemia, fatigue, dyspnea, rash, nausea, bronchitis, upper respiratory infection	Infusion-related reactions, CBC, hepatitis B screening at baseline	Patients should be screened for hepatitis B before therapy initiation Premedicate with acetaminophen, antihistamine, and corticosteroid Infusion rate-escalation required
Rituximab	Hypersensitivity reactions and infusion-related reactions, TLS (especially with large tumor burden), myelosuppression and infection, rare reports of PML, severe skin reactions, myalgias, tachycardia	Infusion-related reactions, CBC, neurologic examination, hepatitis B screening at baseline, electrolytes, HR, BP	Patients should be screened for hepatitis B before therapy initiation Infusion-related reactions may be severe; increase rate of infusion gradually and premedicate with acetaminophen and diphenhydramine Rituximab and hyaluronidase available for subcutaneous injection after 1 full dose of IV rituximab
Antibodies that Target CD22			
Inotuzumab ozogamicin	Myelosuppression, infusion-related reactions, QTc interval prolongation, hepatotoxicity	CBC, ECG, infusion-related reactions, liver function	ADC with a calicheamicin derivative payload Premedicate with a corticosteroid, antipyretic, and antihistamine
Antibodies that Target CD30			
Brentuximab vedotin	Neutropenia, peripheral neuropathy, fatigue, nausea and vomiting, anemia, diarrhea, rash, thrombocytopenia, infusion-related reactions, TLS, rare reports of PML	CBC, symptoms of neuropathy, infusion-related reactions, uric acid levels, electrolytes	ADC with payload MMAE (a microtubule disrupting agent) Adjust dose for renal and hepatic impairment

Antibodies that Target CD33			
Gemtuzumab ozogamicin	Hypersensitivity and infusion-related reactions, hemorrhage	Infusion-related reactions	ADC with a calicheamicin derivative payload Premedicate with a corticosteroid, antihistamine, and acetaminophen
Antibodies that Target CD38			
Daratumumab	Infusion-related reactions, pyrexia, fatigue, upper respiratory tract infection, nausea, myelosuppression	CBC, acute or delayed infusion-related reactions	Type and screen patients prior to starting treatment as daratumumab may interfere with cross-matching and red blood cell antibody screening Premedicate with corticosteroids, antipyretics, and antihistamines; administer post-infusion medications Available as subcutaneous injection in combination with hyaluronidase
Isatuximab	Myelosuppression, infusion-related reactions, hypertension, diarrhea, infection, secondary malignancies	CBC, infusion-related reactions, BP	Premedicate with acetaminophen, H1 and H2 antagonist; also administer dexamethasone prior to administration Antiviral prophylaxis recommended
Antibodies that Target CD52			
Alemtuzumab	Myelosuppression and immunosuppression, autoimmune conditions, infection, infusion-related reactions, nausea and vomiting, fever, hypotension, rash, headache, fatigue, secondary malignancies	CBC, infusion-related reactions, CMV, CD4$^+$ counts, HR, BP, autoimmune symptoms, symptoms of infection	Restricted distribution Patients should be started on antiviral and PJP prophylaxis during and for 6 months post-treatment
Antibodies that Target CD79B			
Polatuzumab vedotin	Peripheral neuropathy, infusion-related reactions, myelosuppression, infections, TLS, hepatotoxicity	CBC, symptoms of neuropathy, infusion-related reactions, uric acid levels, electrolytes, liver function	ADC with payload MMAE (a microtubule disrupting agent) Premedicate with an antihistamine and antipyretic
Antibodies that Target Chemokine Receptor			
Mogamulizumab	Dermatologic reactions, infusion-related reactions, infections, autoimmune complications, complications of allogeneic HSCT	Infusion-related reactions	Administer diphenhydramine and acetaminophen for the first infusion

Antibodies that Target GD2 Receptor			
Dinutuximab	Infections, infusion-related reactions, hypokalemia, hypotension, capillary leak syndrome, neurological ocular toxicity, pain, bone marrow suppression, hemolytic uremic syndrome	CBC, electrolytes, renal function, BP, infusion-related reactions	Premedicate with IV analgesics (such as morphine), an antihistamine, acetaminophen, antiemetics, and IV hydration
Naxitamab	Edema, hypertension, tachycardia, dermatologic toxicity, diarrhea, nausea and vomiting, headache, peripheral neuropathy, anxiety, irritability, cough, fever, infusion-related reactions	BP, HR, infusion-related reactions	Premedications and supportive medications (pain management): 5 days prior to the first infusion in each cycle, initiate a 12-day course (day -4 through day 7) of prophylactic medication for neuropathic pain (eg, gabapentin); give oral opioids 45 to 60 minutes prior to initiation of each infusion with additional IV opioids as needed for breakthrough pain during infusion; consider ketamine for pain not adequately controlled by opioids
Antibodies that Target Nectin-4			
Enfortumab vedotin	Myelosuppression, peripheral neuropathy, ocular toxicity, dermatologic toxicity, alopecia, diarrhea, dysgeusia, decreased appetite, hyperglycemia	CBC, blood glucose, liver function, Child-Pugh score	ADC with payload MMAE (a microtubule disrupting agent) Dose capped at 125 mg Avoid use in Child-Pugh classes B and C
Antibodies that Target EGFR			
Cetuximab, necitumumab, and panitumumab	Rash, paronychial cracking in fingers or toes, asthenia, abdominal pain, nausea, constipation, diarrhea, infusion and hypersensitivity reactions, electrolyte wasting, cardiopulmonary arrest	Electrolytes, infusion-related reactions, dermatologic evaluation	Dose reductions or delays may be required for rash but supportive care should be attempted first Decreased risk of infusion-related reactions with panitumumab and does not appear to be cross-reactive (ie, a patient may receive panitumumab if they react to cetuximab) Monitor patients during treatment for hypomagnesemia, hypocalcemia, and hypokalemia, and for at least 8 weeks following the completion of therapy
Antibodies that Target EGFR and MET			
Amivantamab	Pulmonary toxicity, rash, paronychia, ocular toxicity, infusion-related reactions, nausea and vomiting	Infusion-related reactions, pulmonary symptoms, dermatologic evaluations	A bispecific antibody that binds both EGFR and MET The first 2 infusions should be administered via peripheral line Premedication is required

Antibodies that Target HER2			
Ado-trastuzumab emtansine	Cardiac toxicity, thrombocytopenia, hemorrhage, hepatotoxicity, infusion-related reactions, peripheral neuropathy, ILD, embryo-fetal toxicity	CBC, liver function, pregnancy status, cardiac monitoring (LVEF), pulmonary symptoms	ADC with payload DM1 (a microtubule inhibitor) Ado-trastuzumab emtansine is NOT interchangeable with other antibodies that target HER2
Fam-trastuzumab deruxtecan	Myelosuppression, decrease LVEF, ILD, constipation, diarrhea, decrease appetite, nausea and vomiting	CBC, LVEF, liver function, pulmonary symptoms, fever	ADC with payload DXd (a topoisomerase I inhibitor) Fam-trastuzumab deruxtecan is NOT interchangeable with other antibodies that target HER2
Margetuximab	Alopecia, cardiac toxicity (hypertension and decrease LVEF), abdominal pain, diarrhea, nausea and vomiting, headache, fatigue, fever, infusion-related reactions	LVEF, BP, infusion-related reactions	Consider premedications (including antihistamines, corticosteroids, and antipyretics) with future cycles if a mild to moderate infusion reaction occurs
Pertuzumab	Diarrhea, nausea, alopecia, rash, neutropenia, fatigue, peripheral neuropathy, embryo-fetal toxicity, left ventricular dysfunction, infusion-related reactions	LVEF, infusion-related reactions, pregnancy status	Available in combination with trastuzumab and hyaluronidase as a single subcutaneous injection
Trastuzumab	Cardiac toxicity (congestive cardiomyopathy, usually reversible with medical management), infusion-related reactions, pulmonary toxicity, embryo-fetal toxicity	Infusion-related reactions, cardiac monitoring (LVEF)	Do not administer with anthracyclines because of increased cardiotoxicity Trastuzumab is NOT interchangeable with other antibodies that target HER2 Trastuzumab with hyaluronidase available for subcutaneous injection
Antibodies that Target SLAMF7 (Signaling Lymphocytic Activation Molecule Family 7)			
Elotuzumab	Fatigue, pyrexia, diarrhea or constipation, respiratory infections, peripheral neuropathy, hepatotoxicity, infusion-related reactions, secondary primary malignancies	Liver function, infusion-related reactions, infections	May interfere with the assay used to monitor M-protein which can impact the determination of complete response Premedicate with dexamethasone, diphenhydramine, an H2 antagonist, and acetaminophen
Antibodies that Target TROP2 (Trophoblast Cell-Surface Antigen 2)			
Sacituzumab govitecan	Myelosuppression, nausea and vomiting, alopecia, rash, abdominal pain, fatigue, hypersensitivity reaction	CBC, infusion-related reactions	ADC with payload SN-38 (a topoisomerase I inhibitor) Premedication with corticosteroids, an H1, and H2 antagonist Patients who are homozygous for the UGT1A1*28 allele are at increased risk of toxicity

Antibodies that Target VEGFR			
Bevacizumab	GI perforation, impaired wound healing, hypertension, proteinuria, thrombotic events, hemorrhage, rare reports of RPLS	BP, urine protein, neurologic examination, signs of GI perforation, symptoms of thromboembolism	Withhold 28 days prior to elective surgery. Do not administer for at least 2 weeks following a major surgical procedure and until adequate wound healing
Ramucirumab	GI perforation, impaired wound healing, hypertension, proteinuria, thyroid dysfunction, thromboembolic events, hemorrhage	BP, urine protein, thyroid function, liver function	Withhold 28 days prior to elective surgery. Do not administer for at least 2 weeks following a major surgical procedure and until adequate wound healing
Bispecific T-Cell Engagers			
Blinatumomab	Infusion-related reactions, cytokine release syndrome, neurologic toxicities, infections, fever, headache, peripheral edema, rash, TLS, hepatotoxicity, bone marrow suppression	CBC, liver function, neurological examination, uric acid levels, electrolytes	Premedicate with dexamethasone prior to the first dose of each cycle, prior to a step dose or when restarting therapy after an interruption > 4 hours Administered as a continuous intravenous infusion over 28 days
Fusion Proteins			
Moxetumomab pasudotox	Renal toxicity, infusion-related reactions, electrolyte abnormalities, hemolytic uremic syndrome	Renal function, electrolytes, infusion-related reactions	Premedicate with acetaminophen, an antihistamine, and an H_2 antagonist Consider low-dose aspirin on days 1-8 of each cycle
Ziv-aflibercept	Myelosuppression, diarrhea, proteinuria, increases in liver enzymes, stomatitis, fatigue, hypertension, weight decreased, decreased appetite, epistaxis, abdominal pain, dysphonia, increased serum creatinine, headache, hemorrhage, GI perforation, compromised wound healing, arterial thromboembolic events, fistula formation	BP, urine protein, signs and symptoms of hemorrhage, CBC, liver function, renal function	Hold at least 4 weeks before elective surgery and restart at least 4 weeks after major surgery and after the surgical wound is fully healed
Immunotherapy			
Immune Checkpoint Inhibitors			
Ipilimumab	Fatigue, irAEs (eg, enterocolitis, dermatitis, endocrinopathy, hepatitis), infusion-related reactions (rare)	Thyroid function, electrolytes, liver function, renal function,	Treat severe irAEs with corticosteroids

		dermatologic evaluations, GI symptoms, consider CBC	
Atezolizumab, avelumab, cemiplimab, dostarlimab, durvalumab, nivolumab, and pembrolizumab	Fatigue, irAEs (eg, pneumonitis, colitis, hepatitis, thyroid dysfunction)	Liver function, renal function, thyroid function, GI symptoms	Treat severe irAEs with corticosteroids For avelumab, premedicate with an antihistamine and acetaminophen prior to the first 4 infusions
Cytokines			
Interleukin-2	Flu-like syndrome (fevers, chills, malaise), vascular or capillary leak syndrome (hypotension, pulmonary and peripheral edema), nausea and vomiting, diarrhea, nephrotoxicity, myelosuppression (thrombocytopenia and leukopenia), bacterial infections, CNS toxicities (somnolence and confusion), arrhythmias, rash, itching	Intense monitoring required, electrolytes, liver function, renal function, CBC, thallium stress test, pulmonary function tests, cardiac monitoring during administration, BP, HR	Vasopressor support and fluid resuscitation may be necessary during treatment because of hypotension Pulmonary edema can be managed with cautious use of diuretics; short courses of albumin may also be beneficial Itching may respond to treatment with antihistamines; emollient skin creams or occlusive agents are effective for dry, peeling skin Avoid corticosteroids because they may counteract the antitumor effects of interleukin-2 Patients on beta-blockers will need to be tapered off before initiation of interleukin-2
Therapeutic Vaccines			
Sipuleucel-T	Infusion-related reactions, chills, fatigue, back pain, nausea, joint ache, headache, thromboembolic events have occurred	Infusion-related reaction	Physicians and patients must be registered Premedicate with an antihistamine and acetaminophen For autologous use only
Talimogene laherparepvec	Fatigue, chills, pyrexia, nausea, influenza-like illness, injection-site pain, cellulitis, risk of herpetic infection	Herpetic infections, injection-site complications, immune-mediated events	Administered directly into the cutaneous, subcutaneous, and/or nodal lesion(s) Precautions for accidental exposure of healthcare workers and close contacts Acyclovir and other antiviral medications may interfere with the efficacy
Chimeric Antigen Receptor (CAR) Therapies			
Axicabtagene ciloleucel, brexucabtagene autoleucel,	Hypersensitivity, myelosuppression, hypogammaglobulinemia, secondary malignancies, neurologic toxicities, cytokine release syndrome	CBC, infection, cytokine release syndrome, neurologic	For autologous use only REMS program to mitigate the risk of cytokine release syndrome and neurological toxicities

idecabtagene vicleucel, lisocabtagene maraleucel, tisagenlecleucel		examinations	

[a]Only approximate guidelines can be given. Consult current references before dispensing as not all dose adjustments and monitoring parameters are provided in the table.

Data from Reference 59.

BP, blood pressure; CBC, complete blood count; CHF, congestive heart failure; CMV, cytomegalovirus; CPK, creatinine phosphokinase; CYP, cytochrome P450 isoenzyme; DXd, DX-8951 derivative; GI, gastrointestinal; H1 and H2, histamine 1 and 2; HCC, hepatocellular carcinoma; HHV-8, human herpes virus 8; HIV, human immunodeficiency virus; HR, heart rate; ILD, interstitial lung disease; IM, intramuscular; INR, international normalized ratio; IT, intrathecal; IV, intravenous; MAOI, monoamine oxidase inhibitor; MI, myocardial infarction; MMAE, monomethylauristatin E; PFTs, pulmonary function tests; PJP, pneumocystis jirovecii pneumonia; PML, progressive multifocal leukoencephalopathy; PPIs, proton pump inhibitors; PRES, posterior reversible encephalopathy syndrome; PT, prothrombin time; PTT, partial thromboplastin time; RPLS, reversible posterior leukoencephalopathy syndrome; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

Antimetabolites

Antimetabolites are similar to the nucleotides that make up DNA and RNA. The body mistakes these chemotherapy agents for the naturally occurring nucleotide bases and metabolizes these agents as the natural nucleotides. These chemotherapy agents ultimately disrupt replication and cell division by interfering with the production of nucleic acids, DNA, and RNA. Unfortunately, these compounds are not selective for cancer cells, and rapidly dividing normal cells may be affected. The most common toxicities associated with the antimetabolites are secondary to their effect on rapidly dividing normal cells, such as bone marrow and gastrointestinal tract cells. The three major classes of antimetabolites include pyrimidine analogues, purine analogues, and folate antagonists. Hypomethylating agents are also considered antimetabolites.

Pyrimidine Analogues

Cytarabine

Cytarabine is a cytidine analogue commonly used to treat AML, acute lymphoblastic leukemia (ALL), and NHL. It is phosphorylated to its active phosphates within cancer cells and inhibits DNA polymerase, an enzyme responsible for strand elongation. It is also incorporated directly into DNA, where it inhibits DNA replication and acts as a chain terminator to prevent DNA elongation. Deaminase enzymes, particularly cytidine deaminase, degrade cytarabine and other cytidine analogues.

Cytarabine may be given intravenously or intrathecally. Intrathecal administration allows for cytotoxic concentrations of cytarabine to be maintained in the central nervous system (CNS) for several hours. It may be given to patients with leukemia.

The dose-limiting toxicities are leukopenia and thrombocytopenia. Other common toxicities include nausea, vomiting, mucositis, and diarrhea. Following administration of high-dose cytarabine (greater than 1 g/m^2 per dose), cerebellar syndrome may occur presenting with dysarthria, nystagmus, and ataxia. The risk of cerebellar syndrome is strongly correlated with advanced age and renal dysfunction. Renal dysfunction permits accumulation of high levels of triphosphate, which is believed to be neurotoxic. Hepatic dysfunction, high cumulative doses, and bolus dosing may also increase the risk of neurotoxicity. Conjunctivitis or keratitis is another common toxicity associated with high-dose cytarabine. Prophylactic corticosteroid or saline eye drops should be administered with high-dose cytarabine to minimize irritation. Allopurinol may be given with high-dose cytarabine to minimize the risk of tumor lysis syndrome (TLS), a group of metabolic complications that can occur following the breakdown of dying cancer cells.

Fluoropyrimidines

Fluorouracil (sometimes referred to as 5-FU) is a fluorinated uracil analogue initially synthesized in the late 1950s. It acts as a false pyrimidine and undergoes sequential phosphorylation to a mono-, di-, and triphosphate similar to natural nucleotide bases. In the presence of folates, the monophosphate binds tightly to and interferes with the function of thymidylate synthase. The triphosphate metabolite is incorporated into RNA as a false base and interferes with its function. The interference with both thymidine formation and RNA function contributes to its cytotoxic effects. Fluorouracil is commonly used to treat gastrointestinal tract and head-and-neck cancers.

The dosage and administration influence both the mechanism of action and toxicity profile. With continuous-infusion regimens, the inhibition of thymidylate synthesis plays a greater role, and dose-limiting toxicities include palmar-plantar erythrodysesthesia (PPE) and diarrhea. Comparatively, the incorporation into RNA plays a greater role with intermittent bolus schedules. The dose-limiting toxicity commonly associated with a bolus administration is myelosuppression.

Several pharmacologic strategies have been attempted to increase its cytotoxicity against cancer cells and decrease its toxicity to normal cells. The most common strategy combines fluorouracil with the reduced folate leucovorin. Folates increase the reduced folate pool, stabilize the monophosphate–thymidylate synthase complex, and prolong the inhibition of thymidylate synthase. Clinical trials suggest that combining reduced folates with fluorouracil provides greater anticancer activity and improves tolerability.

Dihydropyrimidine dehydrogenase (DPD) is a pyrimidine catabolic enzyme responsible for about 80% of the catabolism of fluorouracil. Reduced expression of this enzyme has been associated with drug accumulation and serious adverse drug reactons. DPD deficiency is an autosomal recessive genetic disorder, with genetic variation in the *DPYD* gene associated with reduced enzyme activity. DPD deficiency occurs in up to 5% of the overall population. Fluorouracil is contraindicated in patients with known DPD deficiency.

Capecitabine is an oral pyrimidine uracil analogue used to treat breast and colon cancers. Because capecitabine is enzymatically converted to fluorouracil, it shares the same mechanisms of action. Capecitabine is typically taken twice daily with food for the first 14 days of a 21-day treatment cycle. Since chronic twice-daily oral dosing produces sustained fluorouracil levels similar to those observed with continuous infusions, PPE and diarrhea are the dose-limiting toxicities.

Uridine triacetate is a pro-drug of uridine and competitively inhibits fluorouracil-mediated cell damage. It is approved for the emergency treatment of adult and pediatric patients following a fluorouracil or capecitabine overdose, regardless of symptoms. It is also indicated for patients who have received fluorouracil or capecitabine and exhibit early onset, severe, or life-threatening cardiac or CNS toxicity and/or early onset unusually severe adverse drug reactions within 96 hours following exposure. It is not recommended for nonemergent treatment of adverse drug reactions. The safety and efficacy have not been established when more than 96 hours have elapsed following the end of fluorouracil or capecitabine administration. Few adverse drug reactions have been reported, but the most common are vomiting, nausea, and diarrhea.

Gemcitabine

Gemcitabine is a fluorine-substituted deoxycytidine analogue structurally related to cytarabine and is used to treat pancreatic cancer, NSCLC, breast cancer, and urothelial cancer. Its activation and mechanism of action are similar to those of cytarabine. Gemcitabine is incorporated into DNA, where it inhibits DNA polymerase activity. It also inhibits ribonucleotide reductase, which is the enzyme required to convert ribonucleotides into the deoxyribonucleotides needed for DNA synthesis and repair. Compared with cytarabine, gemcitabine achieves intracellular concentrations about 20 times higher, secondary to increased penetration of cell membranes and greater affinity for the activating enzyme deoxycytidine kinase. Gemcitabine that is incorporated into DNA has a prolonged intracellular half-life. Its stereoconfiguration causes another normal base pair to be added next to the fraudulent gemcitabine base pair in the DNA strand. This “masked chain termination” protects the gemcitabine from excision and elimination. Flu-like symptoms, myelosuppression, liver enzyme abnormalities, and dermatologic toxicities are commonly associated with gemcitabine.

Trifluridine and Tipiracil

Trifluridine and tipiracil are combined in a molar ratio of 1:0.5 in one tablet approved for the treatment of metastatic colorectal and gastric cancers. Trifluridine is a thymidine-based nucleoside analogue, and tipiracil is a thymidine phosphorylase inhibitor. Following uptake into cancer cells, trifluridine is incorporated into DNA, interferes with DNA synthesis, and inhibits cell proliferation. Inclusion of tipiracil increases trifluridine exposure by inhibiting its metabolism by thymidine phosphorylase. The dose-limiting toxicity is myelosuppression; patients older than 65 years of age may be at greater risk. Other common toxicities include asthenia/fatigue, nausea, decreased appetite, diarrhea, vomiting, abdominal pain, and pyrexia.

Purine Analogues

Cladribine and Pentostatin

Cladribine and pentostatin are purine nucleoside analogues with slightly different mechanisms of action. Both agents are used to treat hairy cell leukemia. Cladribine is resistant to inactivation by adenosine deaminase and is triphosphorylated to an active form incorporated into DNA that inhibits DNA synthesis and early chain termination. Its anticancer activity is unusual for an antimetabolite, in that it affects both actively dividing and resting cancer cells. Pentostatin is a potent inhibitor of adenosine deaminase. Adenosine deaminase is an enzyme critical in purine base metabolism and is found in high concentrations in lymphatic tissue. Both agents have immunosuppressive effects that place patients at risk for serious opportunistic infections and require the administration of prophylactic antibiotics.

Fludarabine

Fludarabine is an adenine analogue used to treat chronic lymphocytic leukemia (CLL) and indolent NHL. Similar to cytarabine, fludarabine interferes with DNA polymerase, causing chain termination. Fludarabine also incorporates into RNA, resulting in inhibition of transcription. Fludarabine is immunosuppressive; it has been associated with the development of opportunistic infections, secondary to its effect on T cells and subsequent decrease in CD4 counts. It is often given as part of a conditioning regimen prior to HSCT. Prophylactic antibiotics and antiviral medications are recommended and should continue until CD4 counts normalize.

Mercaptopurine and Thioguanine

6-Mercaptopurine and its analogue thioguanine are oral antimetabolites used for the treatment of ALL. These antimetabolites are rapidly converted to ribonucleotides that inhibit purine biosynthesis or undergo purine interconversion reactions needed to supply purine precursors to synthesize nucleic acids. Clinical cross-resistance is generally observed. Both antimetabolites are metabolized by thiopurine methyltransferase (TPMT) and hypoxanthine phosphoribosyl transferase to produce multiple metabolites that contribute to the observed anticancer activity, hepatotoxicity, and myelosuppression. Additionally, nucleoside diphosphate-linked moiety X (nudix)-type motif 15 (NUDT15) catalyzes the conversion of the cytotoxic metabolite into a less toxic compound. Certain genetic alterations within the *TPMT* or *NUDT15* gene can lead to a reduction or loss of enzyme activity. Therefore, patients who are homozygous or heterozygous for a genetic alteration that affects TPMT or NUDT15 activity may experience an accumulation of toxic metabolites and an increased risk of severe myelosuppression. The Clinical Pharmacogenetics Implementation Consortium provides primary dosing recommendations for patients with *TPMT* or *NUDT15* alterations.

6-Mercaptopurine depends on xanthine oxidase for an initial oxidation step. Its metabolism is markedly decreased by coadministration with a xanthine oxidase inhibitor (eg, allopurinol), which may lead to serious adverse drug reactions. If allopurinol is given concurrently with 6-mercaptopurine to minimize TLS, the dose of 6-mercaptopurine must be reduced.

Folate Antagonists

Methotrexate

Methotrexate is commonly used to treat ALL and some lymphomas. It inhibits dihydrofolate reductase (DHFR), which results in the depletion of intracellular pools of reduced folates (tetrahydrofolates) essential for thymidylate and purine synthesis. Folates are essential cofactors for DNA and RNA synthesis and, thus, lack of either thymidine or purines prevents DNA or RNA synthesis.

Chemotherapy regimens may contain low-, intermediate- or high-dose methotrexate and may incorporate methotrexate administered orally, intravenously, or intrathecally. High-dose, defined as doses greater than 500 mg/m^2/dose given intravenously as prophylaxis or treatment of CNS disease, can cause severe myelosuppression and gastrointestinal toxicity. The development of these toxicities is related to both the maximal concentrations and the time that concentrations remain above 0.02 mg/L (50 nmol/L). These effects may be neutralized by exogenously supplying reduced folates, such as leucovorin (folinic acid), which bypasses the metabolic block induced by DHFR inhibitors. Leucovorin should be administered until methotrexate levels fall below the threshold and various dosing algorithms are available. Vigorous hydration and sodium bicarbonate to alkalinize the urine should be given to decrease the risk of renal failure. Patients with third space fluids may require prolonged leucovorin rescue since these fluids influence methotrexate volume of distribution and elimination half-life.

Glucarpidase is approved for the treatment of toxic plasma methotrexate concentrations in patients with delayed methotrexate clearance because of impaired renal function. It is important to note that methotrexate concentrations within 48 hours after glucarpidase administration can only be reliably measured by chromatographic methods. Immunoassays can overestimate methotrexate concentration because of interference from metabolites.

Methotrexate is highly protein bound, and drugs such as sulfonamides, salicylates, phenytoin, and tetracyclines may displace methotrexate from albumin. Increased toxicity may be observed. Nonsteroidal anti-inflammatory drugs and vitamin C may also affect methotrexate disposition and prolong methotrexate elimination half-life. Although the exact mechanism is uncertain, proton pump inhibitors are thought to inhibit methotrexate elimination and potentially increase methotrexate toxicity.

Pemetrexed

Pemetrexed is a multitargeted antifolate that is used to treat nonsquamous NSCLC and mesothelioma. It inhibits at least three biosynthetic pathways in thymidine and purine synthesis. In addition to inhibiting DHFR, it also inhibits thymidine synthase and glycinamide ribonucleotide formyltransferase, decreasing the risk of the development of drug resistance. Severe hematologic toxicity and deaths associated with neutropenic sepsis have been reported in clinical trials: elevated baseline cystathionine or homocysteine concentrations correlate with this unexpected toxicity. Routine supplementation of folic acid and vitamin B_{12} before the initiation of pemetrexed and throughout treatment reduces levels of these substances and lowers the risk of mortality related to neutropenic sepsis. Dexamethasone should be given with pemetrexed to minimize the risk of dermatologic toxicities.

Pralatrexate

Pralatrexate is an antifolate drug approved for patients with relapsed or refractory peripheral T-cell lymphoma. It competitively inhibits DHFR and polyglutamylation by the enzyme folylpolyglutamyl synthetase. This inhibition results in the depletion of thymidine and other synthesis of biological molecules that depends on single carbon transfer. The most common adverse drug reactions resulting in dose reductions are pyrexia, mucositis, febrile neutropenia, sepsis, and thrombocytopenia.

Hypomethylating Agents

Azacitidine and decitabine are nucleoside analogues that demonstrate dose-dependent effects. These analogues exert their effects at lower doses by directly incorporating into DNA and inhibiting DNMT, which leads to cellular differentiation and apoptosis.[14] At higher doses, these agents might cause the formation of covalent adducts between DNMT and the active drug being incorporated into DNA, particularly in cells actively dividing. Hypomethylation also normalizes the function of genes that control cell differentiation and proliferation, promoting normal cell maturation.[14] Decitabine is also available in combination with cedazuridine, a cytidine deaminase inhibitor that impedes the degradation of decitabine and allows for improved systemic exposure following oral administration.

These inhibitors slow the progression of myelodysplastic syndrome (MDS) to AML, reduce transfusion requirements, and allow for the improvement of normal hematopoiesis over time. Azacitidine tablets are approved for the maintenance treatment of AML in patients who achieve complete remission following intensive induction chemotherapy and cannot complete intensive curative treatment. The primary toxicity is myelosuppression, particularly during early phases of treatment as the malignant clone driving the MDS is cleared from the bone marrow, and normal hematopoiesis is slowly restored. As a result, infections occur frequently.

Microtubule-Targeting Drugs

Microtubules are an integral part of the cytoskeleton and help maintain the shape of a cell. These structures are also involved in chromosome separation during mitosis and form the mitotic spindle responsible for separating chromosomes during cell replication. Several chemotherapy agents affect microtubule function, including taxanes, vinca alkaloids, epipodophyllotoxins, epitholones, and macrolides.

Taxanes

Paclitaxel and docetaxel are taxane plant alkaloids with antimitotic activity used to treat many different solid tumors. Paclitaxel and docetaxel both act by binding to tubulin, but they do not interfere with tubulin assembly. Instead, the taxanes promote microtubule assembly and interfere with microtubule disassembly. They induce tubulin polymerization, resulting in formation of inappropriately stable, nonfunctional microtubules. The stability of the microtubules damages cells by disrupting the dynamics of microtubule-dependent structures required for mitosis and other cellular functions. Taxanes also have some nonmitotic actions that can promote cancer cell death, such as inhibition of angiogenesis.

Resistance to the antitumor effects of the taxanes is attributable to alterations in tubulin or tubulin-binding sites or to P-glycoprotein (P-gp)-mediated multidrug resistance. Although paclitaxel and docetaxel have very similar mechanisms of action, cross-resistance between the two chemotherapy agents is incomplete. Myelosuppression and peripheral neuropathy frequently occur with both docetaxel and paclitaxel. Fluid retention is more common with docetaxel, and hypersensitivity reactions may be more frequent with conventional paclitaxel. Both require premedication to decrease the likelihood of hypersensitivity reactions; docetaxel's premedication also reduces fluid retention.

Two paclitaxel formulations are available. The original product (ie, conventional paclitaxel) contains Cremophor and ethanol. The subsequent product (nab-paclitaxel) contains paclitaxel bound to albumin and does not include the Cremophor excipient believed to contribute to hypersensitivity reactions. In clinical trials, nab-paclitaxel has shown comparable activity to conventional paclitaxel with a lower incidence of hypersensitivity reactions. Peripheral neuropathy remains a common adverse event with nab-paclitaxel. Nab-paclitaxel is approved for the treatment of metastatic breast cancer, NSCLC, and pancreatic cancer. The products are not interchangeable, and the doses are not comparable on a mg-to-mg basis.

Cabazitaxel is a semisynthetic derivative of docetaxel that has demonstrated anticancer activity in castrate-resistant prostate cancer that has progressed following treatment with docetaxel-based chemotherapy. Despite having the same mechanism of action, the lack of affinity for P-gp allows cabazitaxel to remain inside the cancer cells, partially accounting for its benefit in the refractory setting. Toxicities and premedications are similar to docetaxel.

Vinca Alkaloids

Vincristine, vinblastine, and vinorelbine are natural alkaloids derived from the periwinkle (vinca) plant. These agents act as mitotic inhibitors or spindle poisons. Although these alkaloids have a very similar structure, they have different activities and patterns of toxicity. These agents are used to treat different cancers. For example, vinblastine may be used to treat testicular cancer and Hodgkin lymphoma; vincristine may be used to treat NHL and Hodgkin lymphoma; and vinorelbine may be used to treat NSCLC and breast cancer. Vinorelbine and vinblastine are associated with dose-limiting myelosuppression, while vincristine is associated with dose-limiting neurotoxicity, including constipation and paralytic ileus. All vinca alkaloids are vesicants upon extravasation; local heat application allows dispersal or dilution of the alkaloid to minimize tissue damage. Vinca alkaloids should never be administered intrathecally, and accidental overdose is associated with a very high mortality rate.

Vinca alkaloids bind to tubulin and disrupt the normal balance between polymerization and depolymerization of microtubules, inhibiting the assembly of microtubules and disrupting microtubule dynamics. This interferes with the formation of the mitotic spindle and causes cells to accumulate in mitosis. These agents also disturb a variety of microtubule-related processes in cells and induce apoptosis. Resistance to the vinca alkaloids develops primarily from P-gp-mediated multidrug resistance, decreasing drug accumulation and retention within cancer cells.

Miscellaneous Antimicrotubule Agents

Eribulin is a fully synthetic antimicrotubule analogue of the macrolide halichondrin B. Eribulin inhibits tubulin polymerization by inhibiting microtubule growth, but it does not shorten or promote microtubule depolymerization. Additionally, eribulin only binds to the β-tubulin subunit and has demonstrated the ability to overcome taxane resistance conferred by β-tubulin mutations. The most common toxicities are similar to other microtubule inhibitors, but eribulin demonstrates a decreased incidence of neuropathy than vincristine and taxanes. Eribulin is approved for the treatment of metastatic breast cancer and unresectable or metastatic liposarcoma.

Ixabepilone is a synthetic epothilone approved for the treatment of metastatic breast cancer. Its binding to microtubules appears distinct from other microtubule inhibitors such as the taxanes. Thus, it has demonstrated activity in taxane-resistant cells. Dose-limiting toxicities are leukopenia and neuropathy, consistent with other microtubule inhibitors. Other toxicities include anemia, thrombocytopenia, diarrhea, myalgia, and alopecia. Premedication with antihistamines must be administered to reduce the risk of hypersensitivity reactions.

Topoisomerase Inhibitors

Topoisomerases (I and II) are essential enzymes involved in maintaining DNA topologic structure during replication. These enzymes cleave DNA strands and form intermediates with the strands during replication, producing a gap through which DNA strands can pass and then reseal the strand breaks. Topoisomerase I produces single-strand breaks, and topoisomerase II produces double-strand breaks. Several important anticancer agents interact with topoisomerase enzymes: camptothecins, anthracyclines, and podophyllotoxins.

Camptothecins

Topotecan and irinotecan, through an active metabolite SN-38, inhibit topoisomerase I enzyme activity. Topoisomerase I enzymes stabilize DNA single-strand breaks and inhibit strand resealing. Topotecan is available for oral and intravenous administration, and it is used to treat ovarian cancer and small cell lung cancer (SCLC). Irinotecan is used for the treatment of colorectal cancer and other gastrointestinal malignancies. SN-38 undergoes metabolism in part by uridine diphosphate-glucuronosyl transferase 1A1 (UGT1A1). Although variant tandem repeats in the promoter of this gene have been associated with a higher risk of diarrhea and neutropenia, genotyping has not been widely adopted in clinical practice. A starting dose reduction should be considered for patients known to be homozygous for the UGT1A1*28 allele, but specific dosing recommendations have yet to be determined. All patients receiving irinotecan are at risk of developing early and/or late diarrhea. Early diarrhea (ie, within 24 hours of irinotecan administration) is a cholinergic effect and may be prevented or treated with atropine, whereas late diarrhea is typically treated with loperamide.

In combination with fluorouracil and leucovorin, liposomal irinotecan is approved for the treatment of patients with metastatic adenocarcinoma of the pancreas whose disease has progressed following gemcitabine-based therapy. The common toxicities associated with irinotecan have been observed with liposomal irinotecan, including gastrointestinal toxicity and myelosuppression.

Anthracyclines

The anthracyclines include doxorubicin, daunorubicin (daunomycin), idarubicin, and epirubicin. These agents share a common, four-membered anthracene ring complex with an attached aglycone or sugar portion. The ring complex is a chromophore and accounts for the intense colors of these derivatives.[15] Anthracyclines are sometimes classified as antitumor antibiotics, but they have multiple mechanisms of action, including intercalation into DNA and inhibition of topoisomerase II. The production of free radicals following their metabolism may also contribute to their anticancer activity. These agents are used to treat many cancers, including leukemias, lymphomas, and multiple solid tumors.

Although the dose-limiting toxicity is myelosuppression, development of cardiomyopathy is a significant concern with these agents. All patients should have a baseline study to evaluate left ventricular ejection fraction (LVEF). Since the probability of congestive heart failure increases with the cumulative dose, a maximum cumulative dose has been suggested for each anthracycline. The relatively low level of defensive enzymes found in cardiac muscle that scavenge against oxygen-free radicals may account for the relative risk of cardiomyopathy compared to toxicity in other organs. Oxygen-free-radical formation likely contributes to extravasation injury associated with these agents, as well. When extravasated (ie, leaked from the intravascular space into the surrounding tissues), anthracyclines are vesicants known to cause significant tissue damage, including blistering and necrosis. Other common toxicities include nausea, vomiting, and alopecia. Doxorubicin also causes a red discoloration of the urine. Resistance to anthracyclines is usually secondary to P-gp-mediated multidrug resistance, but altered topoisomerase II activity may also contribute to the development of resistance.

Liposomal formulations of both doxorubicin and daunorubicin were developed to improve the safety profile of these agents while maintaining their efficacy. A liposomal combination product containing daunorubicin and cytarabine is also available in a fixed 1:5 molar ratio, which is approved for the treatment of AML.

Mitoxantrone has been identified as an anthracendione. It was synthesized to develop a chemotherapy agent with comparable antitumor activity to doxorubicin but with an improved safety profile. Similar to the anthracyclines, mitoxantrone is an intercalating topoisomerase II inhibitor, but its potential for free-radical formation is much less than that of the anthracyclines. This decreased tendency for free-radical formation may explain the reduced risks of cardiac toxicity and ulceration after extravasation. Mitoxantrone may be used with other anticancer agents to treat leukemias and lymphomas. Common toxicities include nausea, vomiting, alopecia, and blue discolored urine.

Etoposide

Etoposide is a semisynthetic podophyllotoxin derivative that binds to tubulin and interferes with microtubule formation. Etoposide also damages cancer cells by causing strand breakage through inhibition of topoisomerase II. Resistance may be caused by differences in topoisomerase II levels, increased cell ability to repair strand breaks, or increased levels of P-gp. Etoposide is cell-cycle phase-specific and arrests cells in the S or early G_2

phase. As a result, activity is much greater when administered in divided doses over several days rather than in large single doses. Etoposide may be used to treat testicular cancer and SCLC. Toxicities include dose-limiting myelosuppression, as well as nausea, vomiting, and alopecia.

Alkylating Agents

The alkylating agents are among the oldest and most widely used class of chemotherapy agents. Their clinical use evolved from the observation of myelosuppression and lymph node shrinkage in soldiers exposed to sulfur mustard gas warfare during World War I. In an effort to develop similar agents that might be useful in treating lymphomas, less reactive derivatives were synthesized. Clinical trials confirmed their anticancer activity in the mid-1940s.

All alkylating agents work by covalently bonding to highly reactive alkyl groups or substituted alkyl groups with nucleophilic groups of proteins and nucleic acids. Some agents react directly with biologic molecules, but others form an intermediate compound that reacts with these molecules. The most common binding site for alkylating agents is the seven-nitrogen group of the DNA base guanine. These covalent interactions result in cross-linking between two DNA strands or between two bases in the same DNA strand and prevent the separation of DNA strands that need to occur during replication. Reactions between DNA and RNA and between drugs and proteins may also occur. Alkylating agents are cell-cycle phase-nonspecific, but their greatest effect is seen in rapidly dividing cells.

As a class, alkylators are cytotoxic, mutagenic, teratogenic, carcinogenic, and myelosuppressive. Resistance to these chemotherapies can occur from increased DNA repair capabilities, decreased entry into or accelerated exit from cells, increased inactivation inside cells, or lack of cellular mechanisms to result in cell death after DNA damage. They are inactivated by hydrolysis, making spontaneous degradation an important component of their elimination.[16]

Nitrogen Mustards

Bendamustine

Bendamustine is an alkylating agent with a benzimidazole ring that demonstrates only partial cross-resistance in vitro with other alkylating agents.[17] It is used primarily to treat lymphoid malignancies, such as CLL and NHL. Bendamustine is incompatible with polycarbonate or acrylonitrile-butadiene-styrene found in syringes and adapters and has been shown to minimize the integrity of these supplies. Typical adverse drug reactions associated with alkylating agents have been observed with bendamustine, but it appears to cause less alopecia.

Cyclophosphamide and Ifosfamide

Cyclophosphamide and ifosfamide are nitrogen mustard derivatives and are widely used to treat solid tumors and hematologic malignancies. These mustards are closely related in structure, clinical use, and toxicity. Neither agent is active in its parent form and must be activated by cytochrome P450 enzymes. The cytochrome P450-mediated metabolites 4-hydroxycyclophosphamide and 4-hydroxyifosfamide are also cytotoxic compounds. Acrolein, a metabolite of cyclophosphamide and ifosfamide, has little anticancer activity but is responsible for hemorrhagic cystitis associated with ifosfamide and high-dose cyclophosphamide. Mesna is used to reduce the incidence of hemorrhagic cystitis by supplying a free thiol group that binds to and deactivates acrolein. Encephalopathy after ifosfamide can occur within 48 to 72 hours after the infusion and is generally reversible once the infusion is stopped. Methylene blue has been suggested to manage neuropathy, but data is lacking to support its routine use. The increased production of dechloroethylated metabolites after administering ifosfamide compared with cyclophosphamide may explain the increased risk of CNS toxicity associated with ifosfamide.

Melphalan

Originally approved in the 1960s, melphalan is one of the oldest chemotherapy agents still used in clinical practice. It is indicated for the palliative treatment of patients with multiple myeloma and as a high-dose conditioning regimen before HSCT. Over 50 years after melphalan's approval, melphalan flufenamide became the first peptide-drug conjugate approved by the US Food and Drug Administration (FDA). The lipophilic properties of melphalan flufenamide allow for passive distribution into cells where it is hydrolyzed to melphalan.[18] Melphalan flufenamide is given in combination with dexamethasone and is approved for patients with relapsed or refractory multiple myeloma but is not indicated as part of a conditioning regimen. Serious adverse drug reactions include myelosuppression, infections, and secondary malignancies.

Nitrosoureas

Carmustine and Lomustine

Carmustine and lomustine are characterized by their lipophilicity and ability to cross the blood-brain barrier; both agents are used to treat brain cancers. Carmustine is also used to treat multiple myeloma and lymphoma and in preparation for an HSCT. It is available as an intravenous preparation and a drug-impregnated biodegradable wafer for direct application to the tumor cavity after surgical resection of brain tumors. Both agents cause dose-limiting myelosuppression, but the nadir is typically delayed to 4 to 6 weeks after administration. The nitrosoureas decompose to reactive alkylating metabolites and isocyanate compounds that have several effects on reproducing cells.[19]

Nonclassic Alkylating Agents

Several other chemotherapy agents appear to act as alkylators, although their structures do not include the classic alkylating groups. These agents are capable of binding covalently to cellular components and include procarbazine, dacarbazine, temozolomide, and platinum analogues.[19]

Dacarbazine and Temozolomide

Dacarbazine and temozolomide are commonly classified as triazenes and undergo demethylation to the same active intermediate (monomethyl triazeno-imidazole-carboxamide, or MTIC) that interrupts DNA replication by causing methylation of guanine. Unlike dacarbazine, temozolomide does not require the liver for activation and is chemically degraded to monomethyl triazeno-imidazole-carboxamide at physiologic pH. Both agents inhibit DNA, RNA, and protein synthesis.[19]

Important pharmacokinetic differences exist between these two agents. Dacarbazine is poorly absorbed and must be administered by intravenous infusion. Temozolomide is rapidly absorbed after oral administration; it demonstrates nearly 100% bioavailability under fasted conditions. Dacarbazine penetrates the CNS poorly, but temozolomide readily crosses the blood-brain barrier, achieving therapeutically active concentrations in cerebrospinal fluid and brain tumor tissues. Temozolomide is approved for the treatment of glioblastoma, and dacarbazine used to treat Hodgkin lymphoma. Common adverse drug reactions include nausea and vomiting, alopecia, and myelosuppression.

Platinum Analogues

The platinum derivatives—cisplatin, carboplatin, and oxaliplatin—are chemotherapy agents with remarkable usefulness in cancer treatment. Recognition of cisplatin's cytotoxic activity resulted from a serendipitous observation that bacterial growth in culture was altered when an electric current was delivered to the media through platinum electrodes. The growth change was noted to be similar to that produced by alkylating agents and radiation. It was found that a platinum–chloride complex, now known as cisplatin, generated by the current was responsible for the changes. Carboplatin is a structural analogue of cisplatin in which a carboxycyclobutane moiety replaces the chloride groups of the parent compound. It shares a similar spectrum of clinical activity with cisplatin, and cross-resistance is common. Oxaliplatin is an organoplatinum compound in which the platinum is complexed with an oxalate ligand as the leaving group and to diaminocyclohexane. Its spectrum of activity differs substantially from the other platinum compounds and includes notable activity against colorectal cancers.

The cytotoxicity of the platinum derivatives depends on platinum binding to DNA and the formation of intrastrand cross-links or adducts between neighboring guanines. These intrastrand links cause a major bending of the DNA. These agents may cause cellular damage by distorting the normal DNA conformation and preventing bases normally paired from lining up with each other. Interstrand cross-links also occur.

The aquated species differ among these platinum compounds, but all of these species contribute to anticancer activity. The cytotoxic form of cisplatin is the aquated species in which hydroxyl groups or water molecules replace the two chloride groups. This reaction occurs readily in low chloride concentrations, such as the concentrations present within cells, and produces a positively charged compound that can react with DNA. The aquated species is responsible for both the efficacy and toxicity of cisplatin. Carboplatin also undergoes aquation but at a slower rate. Oxaliplatin becomes active when the oxalate ligand is displaced in physiologic solutions.[19]

Resistance to the therapeutic effects of platinum compounds may occur through several mechanisms. The ability to repair platinum-induced DNA damage may be increased, or the compounds may be inactivated by increased intracellular glutathione levels, metallothioneins, or other thiol-containing proteins. Altered uptake into cells may also affect sensitivity to platinum compounds.

The dose-limiting toxicities differ substantially among these compounds. Cisplatin can cause serious nephrotoxicity, ototoxicity, peripheral neuropathy, emesis, and anemia, but its significant anticancer activity in many tumors makes it a valuable agent despite these toxicities. Most of these toxicities can be prevented or managed with aggressive supportive care measures. Intravenous hydration, mannitol, and diuretics have been used to minimize the risk of nephrotoxicity, but it appears intravenous hydration alone is adequate. In contrast, carboplatin administration is limited by hematologic toxicity. Patients with compromised renal function require dose reductions to limit myelosuppressive toxicity. The most widely used dosage schema, the Calvert formula, uses a target area-under-the-curve and renal and nonrenal parameters to estimate the carboplatin dose. Carboplatin's potential to cause renal damage, peripheral neuropathy, and ototoxicity is much less than comparable cisplatin doses. Oxaliplatin is not nephrotoxic or ototoxic, but it can cause peripheral neuropathies and unique cold-induced neuropathies. Intravenous calcium and magnesium were commonly used to minimize the risk of neuropathy. Still these measures do not appear to decrease the risk of acute neurotoxicity or cumulative sensory neurotoxicity based on the results of a controlled trial.[20] All of the platinum derivatives have the potential to cause hypersensitivity reactions, including anaphylaxis after a threshold exposure is reached. Desensitization protocols may be successful in reestablishing tolerance to these agents.

Trabectedin and Lurbinectedin

Both trabectedin and lurbinectedin (an analogue of trabectedin) are alkylating agents that bind guanine residues in the minor groove of DNA. Subsequently, adducts form and cause a bending of the DNA helix toward the major groove. Trabectedin is approved for the treatment of patients with unresectable or metastatic soft tissue sarcoma who have received a prior anthracycline-containing regimen, whereas lurbinectedin is indicated for metastatic SCLC following progression with platinum-based therapy. Warnings associated with both agents include myelosuppression, hepatotoxicity, and embryo-fetal toxicity. Additionally, trabectedin has been associated with rhabdomyolysis, cardiomyopathy, and capillary leak syndrome.

Endocrine Therapies

Endocrine therapies are perhaps the earliest successful approach to target the growth processes of cancer cells. Endocrine manipulation is an option for managing cancers in which growth is under gonadal hormonal control, such as breast, prostate, and endometrial cancers. These cancers may regress if the feeding hormone is eliminated or antagonized. Major organ system toxicity is uncommon from endocrine therapies. These therapies are discussed in detail in Chapters 151, "Breast Cancer," and 154, "Prostate Cancer."

Corticosteroids

Corticosteroids are also useful anticancer therapies because of their lymphotoxic effects. These agents are primarily used to treat hematologic malignancies and are also given in combination with chemotherapy for prostate cancer. In addition to their cytotoxic effects, corticosteroids have many other applications as part of supportive care measures and management of oncologic emergencies. Short-term corticosteroid regimens are generally well tolerated.

Therapeutic Radiopharmaceuticals

An oncology therapeutic radiopharmaceutical is an agent that contains a radionuclide and is used to treat cancer or palliate tumor-associated symptoms. Radioisotopes can emit either alpha or beta particles as their payload.[21] Alpha emitters have high energy and travel only the length of a few cell diameters resulting in double-strand DNA breaks of adjacent cells. In contrast, beta emitters have lower energy and travel the length of hundreds of cell diameters. As a result, these agents affect the cancer cells they bind and other cells within the path length of the radioisotope's emissions (ie, bystander effect). Additionally, some radioisotopes emit gamma radiation with no mass or charge and can travel further than alpha or beta particles.

Ibritumomab Tiuxetan

Ibritumomab tiuxetan is a radioimmunoconjugate that consists of the murine anticluster of differentiation (CD)20 antibody ibritumomab and a linker chelator tiuxetan that allows the attachment of yttrium-90 (active radiotherapy). This therapeutic radiation isotope selectively delivers beta particles to B-cells that express the CD20 antigen. Consequently, ibritumomab tiuxetan can induce cell death in CD20-positive and -negative cancer cells while also inducing antibody-dependent cell-mediated cytotoxicity (ADCC), complement-dependent cytotoxicity (CDC), and apoptosis. These processes are described later in the chapter. Ibritumomab tiuxetan is indicated for the treatment of low-grade or follicular B-cell NHL. The therapeutic regimen consists of two steps: rituximab is administered on day 1, and about one week later (day 7, 8, or 9), an additional dose of rituximab is administered, followed by yttrium-90-ibritumomab within 4 hours after completion of the rituximab infusion.

Adverse drug reactions include severe infusion-related reactions and myelosuppression. Ibritumomab tiuxetan results in prolonged thrombocytopenia and neutropenia, and dose modifications are necessary based on baseline neutrophil and platelet blood counts. The median duration of thrombocytopenia and neutropenia were 24 and 22 days, respectively. Monitoring and managing cytopenias and their complications is necessary for up to 3 months after completing treatment.

Iobenguane I 131

Iobenguane is a molecule structurally similar to norepinephrine and is therefore involved in the same uptake pathways. Labeled with I 131, this agent targets the norepinephrine transporter and is a beta emitter. Two rare tumors, pheochromocytoma and paraganglioma, express high levels of norepinephrine on their cell surfaces. When iobenguane I 131 is administered, it accumulates in these tumor cells allowing the radioisotope to cause cell death and tumor necrosis. Of note, this agent is only approved for patients with an iobenguane positive scan.

Before administration of iobenguane I 131, patients should receive thyroid-blocking medication. Additionally, medications that reduce catecholamine uptake or deplete stores should not be administered concurrently with iobenguane I 131 as they may interfere with the efficacy. The most common toxicities include myelosuppression, fatigue, hypertension, nausea, and vomiting.

Lutetium Lu 177 Dotatate

Lutetium Lu 177 dotatate is a radiolabeled somatostatin analogue that emits beta and gamma radiation and is approved for the treatment of somatostatin receptor-positive gastroenteropancreatic neuroendocrine tumors (GEP-NET). After binding to somatostatin receptor-expressing cells, such as GEP-NET cells, lutetium Lu 177 is taken up into the cell where the beta emission induces cellular damage.

Special precautions should be taken with the administration of somatostatin analogues before lutetium Lu 177. An amino acid solution must be administered before, during, and after lutetium Lu 177 to decrease reabsorption of the radiopharmaceutical through the proximal tubules, thereby reducing the radiation exposure to the kidneys. In addition, patients must be advised on minimizing exposure to contacts. Reported adverse drug reactions include increased hepatic enzymes, hyperglycemia, hypokalemia, nausea, and vomiting. Patients should also be monitored for neuroendocrine hormonal crisis.

Radium Ra 223 dichloride

Radium Ra 223 dichloride (ie, radium-223) is an alpha emitter, which is indicated for the treatment of patients with castration-resistant prostate cancer who have symptomatic bone metastases and no known visceral metastatic disease. Radium-223 mimics calcium and forms complexes with hydroxyapatite at areas of increased bone turnover, such as bone metastases. Alpha particles are then emitted, resulting in DNA breaks and an antitumor effect. Toxicities of radium-223 include bone marrow suppression, gastrointestinal adverse drug reactions, dehydration, and potentially increased risk of fractures in select patients.

Miscellaneous Agents

Arsenic Trioxide

Arsenic is an organic element and a well-known poison that is an effective treatment for acute promyelocytic leukemia, or APL. As an anticancer agent, arsenic trioxide acts as a differentiating agent, inducing the growth progression of cancer cells into mature, more normal cells. It also induces apoptosis. Notable adverse drug reactions associated with arsenic trioxide include QTc prolongation, hepatotoxicity, and differentiation syndrome. Previously known as “retinoic acid syndrome,” differentiation syndrome is a potentially fatal complication of arsenic trioxide. It has been reported with other agents, including tretinoin, enasidenib, ivosidenib, and gilteritinib, which are discussed later in the chapter. This syndrome, which is thought to be caused by a rapid release of cytokines, may present with fever, difficulty breathing, edema, weight gain, and hypotension and must be rapidly treated with corticosteroids.

Asparaginase

L-Asparaginase is unique among anticancer agents in its unusual mechanism of action, source, and patterns of toxicity. It is an enzyme produced by *Escherichia coli* or *Erwinia chrysanthemi*. L-Asparagine is a nonessential amino acid that can be synthesized by most mammalian cells except cells with certain lymphoid malignancies, which have no or limited synthetase levels required for L-asparagine formation. L-Asparagine is degraded by the enzyme L-asparaginase, which depletes existing supplies and inhibits protein synthesis.

Multiple asparaginase products are commercially available. Recombinant asparaginase (*Erwinia*) is produced by fermentation of a genetically engineered *Pseudomonas* bacterium. Pegaspargase and calaspargase pegol are modified versions of L-asparagine conjugated to monomethoxypolyethylene glycol which permits a longer half-life and therefore less frequent administration. All of these products are approved to treat patients with ALL when used as part of a combination chemotherapy regimen. Additionally, recombinant asparaginase (*Erwinia*) is approved to treat patients with lymphoblastic lymphoma. Increased L-asparagine synthetase activity within cancer cells causes treatment resistance. Severe toxicities include anaphylaxis, thrombosis, pancreatitis, glucose intolerance, hemorrhage, and hepatotoxicity.

Bleomycin

Bleomycin is an antitumor antibiotic used with other anticancer agents to treat Hodgkin lymphoma and testicular cancer. It is also used for pleurodesis to prevent a pleural effusion recurrence. Bleomycin is a mixture of peptides from fungal *Streptomyces* species. Its strength is expressed in units of drug activity, and one unit is roughly equal to 1 mg of polypeptide protein. The predominant peptide is bleomycin A2, which makes up about 70% of the commercial drug product. Its cytotoxicity is secondary to DNA strand breakage, which it produces via free-radical formation. Cytotoxicity depends on the binding of the bleomycin–iron complex to DNA. The bleomycin–iron complex then reduces molecular oxygen to free oxygen radicals that cause primarily single-strand breaks in DNA. Bleomycin has greatest effect on cells in the G2 and M phases of the cell cycle.

Bleomycin is inactivated within cells by the enzyme aminohydrolase. This enzyme is widely distributed but is present in only low concentrations in the skin and the lungs, explaining the predominant toxicities of bleomycin to those sites. Therefore, baseline pulmonary function tests and monitoring for pulmonary toxicity are necessary. The risk of pulmonary toxicity increases with age over 70 years and cumulative lifetime bleomycin doses 400 units or higher. The presence of hydrolase enzymes in cancer cells is the primary mechanism of resistance to bleomycin. As a result, cells can also become resistant by repairing the DNA breaks produced by bleomycin.

Hydroxyurea

Hydroxyurea is a unique drug that inhibits ribonucleotide reductase. Cells accumulate in the S phase because DNA synthesis is inhibited, and only abnormally short DNA strands are produced. This anticancer agent was used to treat chronic myeloid leukemia (CML) because of its ability to cause a rapid decline in white blood cells.

Lanreotide

As an octapeptide analogue of somatostatin, the mechanism of lanreotide is believed to be similar to that of natural somatostatin through the inhibition of neuroendocrine functions. Somatostatin analogues are commonly used to treat hypersecretion syndromes associated with neuroendocrine tumors, but only recently have been proven to have an antitumor effect associated with prolonged progression-free survival. Lanreotide is approved for the treatment of unresectable, well or moderately differentiated, locally advanced, or metastatic GEP-NET. Common toxicities include abdominal pain, musculoskeletal pain, vomiting, headache, injection site reaction, and hypertension. In addition, patients should be monitored for hypoglycemia, hyperglycemia, and gallstones.

Mitomycin

Mitomycin, also known as mitomycin C, is a natural product classified as an antitumor antibiotic. It has similarities to nitrogen mustards and may function as an alkylating agent, although its toxicity pattern differs from conventional alkylating agents. Mitomycin may be given intravenously in combination with other chemotherapy agents to treat gastric or pancreatic cancer. When given by this route of administration, delayed myelosuppression may occur, so treatment is typically given every 6 weeks. Mitomycin may also be given as an instillation directly into the bladder (ie, intravesical instillation) for the treatment of localized bladder cancer. Additionally, a ureteral gel formulation is available, which is administered via a ureteral catheter or nephrostomy tube to treat upper tract urothelial cancer.

Omacetaxine Mepesuccinate

Omacetaxine mepesuccinate is a natural ester of the alkaloid cephalotaxine. It inhibits protein translation and thus prevents the initial elongation step of protein synthesis. It is given subcutaneously for treatment of patients with CML who have failed two or more approved therapies for this disease. Additionally, synergy with these approved therapies has been demonstrated in a few clinical studies, and additional combination trials are ongoing. Adverse drug reactions include myelosuppression, hemorrhage, and hyperglycemia.

Retinoids

Three retinoids are available to treat patients with cancer. Tretinoin (all-trans-retinoic acid), a naturally occurring derivative of vitamin A (retinol), is used to treat acute promyelocytic leukemia. Other retinoids indicated for the treatment of cancers include alitretinoin (9-cis-retinoic acid) gel for topical management of Kaposi's sarcoma lesions and bexarotene gel or capsules for treatment of cutaneous T-cell lymphoma.

Retinoids are classified as morphogens, small molecules released from one type of cell that can affect the growth and differentiation of neighboring cells. Their normal roles in the human body are to induce differentiation of some cells, stop the differentiation of others, and both suppress and induce apoptosis in different cell types. Their diverse actions come from the diversity of their receptors. The two classes of retinoid receptors are retinoid X receptors and retinoic acid receptors. Retinoid X receptors are versatile; they bind to retinoic acid receptors and to other nuclear receptors, such as thyroid hormone receptors. After being activated, the receptors act as transcription factors that regulate the expression of genes that control cellular growth and differentiation.

Tretinoin binds primarily to the retinoic acid-α receptors. Alitretinoin is considered a pan-agonist, which means that it binds to all known retinoid receptors, producing diverse regulatory effects. Bexarotene is synthetic and is classed as a rexinoid. It is the first retinoid X receptor–selective retinoid agonist.

The common adverse drug reactions differ for these three agents. Tretinoin may be associated with differentiation syndrome. Alitretinoin is associated with pain, itching, and rash, and bexarotene is associated with skin reactions, thyroid disorders, hypercholesterolemia, and hyperlipidemia.

Thalidomide, Lenalidomide, and Pomalidomide

Thalidomide, the infamous drug that caused severe limb deformities when used by pregnant individuals as a nonprescription sedative in the 1960s, is approved to treat leprosy and multiple myeloma. Thalidomide is a glutamic acid derivative and is broadly classified as an immunomodulatory drug. Lenalidomide and pomalidomide are analogues of thalidomide with similar therapeutic activity but different adverse drug reaction profiles. Lenalidomide is approved for the treatment of multiple myeloma, transfusion-dependent anemia caused by MDS with a specific mutation, follicular lymphoma, marginal zone lymphoma, and mantle cell lymphoma. Pomalidomide is approved for the treatment of multiple myeloma and Kaposi sarcoma.

These drugs have many potential mechanisms of action, but the most important is angiogenesis inhibition, which is also linked to their teratogenic effects. Other possible mechanisms include direct inhibition of cancer cells, free radical oxidative damage to DNA, interference with adhesion of cancer cells, inhibition of TNF-α production, or alteration of cytokine secretion that affects the growth of cancer cells.
